Common human-biting fleas include the dog and cat fleas (*Ctenocephalides* species) and the rat flea (*Xenopsylla cheopis*), which infest their respective hosts and their nests and resting sites. Sensitized persons develop erythematous pruritic papules (*papular urticaria*) and occasionally vesicles and bacterial superinfection at the site of the bite. Symptom-based treatment consists of antihistamines, topical glucocorticoids, and topical antipruritic agents.

Flea infestations are eliminated by removal and treatment of animal nests, frequent cleaning of pet bedding, and application of contact and systemic insecticides to pets and the dwelling. Flea infestations in the home may be abated or prevented if pets are regularly treated with veterinary antiparasitic agents, insect growth regulators, or chitin inhibitors.

Tunga penetrans, like other fleas, is a wingless, laterally flattened insect that feeds on blood. Also known as the chigoe flea, sand flea, or jigger (not to be confused with the chigger), it occurs in tropical regions of Africa and the Americas. Adult female chigoes live in sandy soil and burrow under the skin, usually between toes, under nails, or on the soles of bare feet. Gravid chigoes engorge on the host's blood and grow from pinpoint to pea size during a 2-week interval. They produce lesions that resemble a white pustule with a central black depression and that may be pruritic or painful. Occasional complications include tetanus, bacterial infections, and autoamputation of toes (*ainhum*). Tungiasis is treated by removal of the intact flea with a sterile needle or scalpel, tetanus vaccination, and topical application of antibiotics.

HEMIPTERAN / HETEROPTERAN (TRUE BUG) BITES

Most true bugs feed on plants, but some are predaceous or feed on blood. They may inflict bites in order to feed or in defense that produce allergic reactions and are sometimes painful. Bites of the cone-nose or "kissing bugs" (family Reduviidae) tend to occur at night and are painless. Reactions to such bites depend on prior sensitization and include tender and pruritic papules, vesicular or bullous lesions, extensive urticaria, fever, lymphadenopathy, and (rarely) anaphylaxis. Bug bites are treated with topical antipruritics or oral antihistamines. Persons with anaphylactic reactions to reduviid bites should keep an epinephrine kit available. Some reduviids transmit *Trypanosoma cruzi*, the agent of New World trypanosomiasis (Chagas disease) **(Chap. 222)**.

The cosmopolitan and tropical bedbugs (*Cimex lectularius and C. hemipterus*) hide in crevices of mattresses, bed frames and other furniture, walls, and picture frames and under loose wallpaper, actively seeking blood meals at night. Bedbug populations have resurged, recently attaining levels and spreading to an extent not encountered since the mid-twentieth century. These bugs are now a common pest in homes, dormitories, and hotels; on cruise ships; and even in medical facilities. Their bite is painless, but minutes to days later, sensitized persons develop erythema, itching, and wheals around a central hemorrhagic punctum. Bedbugs are not known to transmit pathogens in nature.

CENTIPEDE BITES AND MILLIPEDE DERMATITIS

The fangs of centipedes of the genus *Scolopendra* can penetrate human skin and deliver a venom that produces intense burning pain, swelling, erythema, and sterile lymphangitis. Dizziness, nausea, and anxiety are described occasionally, and rhabdomyolysis and renal failure have been reported. Treatment includes washing of the site, application of cold dressings, oral analgesic administration or local lidocaine infiltration, and tetanus prophylaxis.

Millipedes are docile and do not bite, but some secrete defensive fluids that may burn and discolor human skin. Affected skin turns brown overnight and may blister and exfoliate. Secretions in the eye cause intense pain and inflammation that can result in corneal ulcers and even blindness. Management includes irrigation with copious amounts of water or saline, use of analgesics, and local care of denuded skin.

CATERPILLAR STINGS AND DERMATITIS

Caterpillars of several moth species are covered with hairs or spines that produce mechanical irritation and may contain or be coated with venom. Contact with these caterpillars or their hairs may lead to erucism (a pruritic urticarial or papular rash) or caterpillar envenomation. The response typically consists of an immediate burning sensation followed by local swelling and erythema and occasionally by regional lymphadenopathy, nausea, vomiting, and headache. A rare reaction to a South American caterpillar, *Lonomia obliqua*, can cause disseminated coagulopathy and fatal hemorrhagic shock. In the United States, dermatitis is most often associated with caterpillars of the io, puss, saddleback, and brown-tail moths. Even contact with detached hairs of other caterpillars, such as gypsy moth larvae, can later produce erucism. Spines may be deposited on tree trunks or drying laundry or may be airborne and cause irritation of the eyes and upper airways. Treatment of caterpillar stings consists of repeated application of adhesive or cellophane tape to remove the hairs, which can then be identified microscopically. Local ice packs, topical glucocorticoids, and oral antihistamines relieve symptoms.

BEETLE VESICATION AND DERMITITIS

Several families of beetles have independently developed the ability to produce chemically unrelated vesicating toxins. When disturbed, blister beetles (family Meloidae) exude cantharidin, a low-molecular-weight toxin that produces thin-walled blisters (≤5 cm in diameter) 2–5 h after contact. The blisters are not painful or pruritic unless broken and resolve without treatment in ≤10 days. Nephritis may follow unusually heavy cantharidin exposure. The hemolymph of certain rove beetles (Staphylinidae) contains pederin, a potent vesicant. When these beetles are crushed or brushed against the skin, the released fluid causes painful, red, flaccid bullae. These beetles occur worldwide but are most numerous and problematic in parts of Africa (where they are called "Nairobi fly") and southwestern Asia. Ocular lesions may develop after impact with flying beetles at night or unintentional transfer of the vesicant on the fingers. Treatment is rarely necessary, although ruptured blisters should be kept clean and bandaged.

Larvae of common carpet beetles are adorned with dense arrays of ornate hairs called *hastisetae*. Contact with these larvae or their setae results in delayed dermal reactions in sensitized individuals. The lesions are commonly mistaken as bites of bedbugs.

DELUSIONAL INFESTATIONS

The groundless conviction that one is infested with arthropods or other parasites (Ekbom's syndrome, delusory parasitosis, delusions of parasitosis, and perhaps Morgellons syndrome) is extremely difficult to treat and, unfortunately, is not uncommon. Patients describe uncomfortable sensations of something moving in or on their skin. Excoriations and self-induced ulcerations typically accompany the pruritus, dysesthesias, and imaginary insect bites. Patients often believe that some invisible or as yet undescribed creatures are infesting their skin, clothing, homes, or environment in general. Frequently, patients submit as evidence of infestation specimens that consist of plant-feeding and nonbiting peridomestic arthropods, pieces of skin, vegetable matter, lint, and other inanimate detritus. When evaluating a patient with possible delusional parasitosis, it is imperative to rule out true infestations and bites by arthropods, endocrinopathies, sensory disorders due to neuropathies, opiate and other drug use, environmental irritants (e.g., fiberglass threads), and other causes of tingling or prickling sensations. Frequently, such patients repeatedly seek medical consultations, resist alternative explanations for their symptoms, and exacerbate their discomfort by self-treatment. Long-term pharmacotherapy with pimozide or other psychotropic agents has been more helpful than psychotherapy in treating this disorder. Patients with delusory parasitosis often develop the unshakeable conviction that they are infested by a previously unknown pathogen, while their personal lives, family support, and employment collapse around them.

453 Altitude Illness

Buddha Basnyat, Geoffrey Tabin

EPIDEMIOLOGY

Mountains cover one-fifth of the earth's surface; 140 million people live permanently at altitudes ≥2500 m, and 100 million people travel to high-altitude locations each year. Skiers in the Alps or Aspen; tourists to La Paz, Ladakh, or Lahsa; religious pilgrims to Kailash-Manasarovar or Gosainkunda; trekkers and climbers to Kilimanjaro, Aconcagua, or Everest; miners working in high-altitude sites in South America; and military personnel deployed to high-altitude locations are all at risk of developing acute mountain sickness (AMS), high-altitude cerebral edema (HACE), high-altitude pulmonary edema (HAPE), and other altitude-related problems. AMS is the benign form of altitude illness, whereas HACE and HAPE are life-threatening. Altitude illness is likely to occur above 2500 m but has been documented even at 1500–2500 m. In the Mount Everest region of Nepal, ~50% of trekkers who walk to altitudes >4000 m over ≥5 days develop AMS, as do 84% of people who fly directly to 3860 m. The incidences of HACE and HAPE are much lower than that of AMS, with estimates in the range of 0.1–4%. Finally, reentry HAPE, which in the past was generally limited to highlanders (long-term residents of altitudes >2500 m) in the Americas, is now being seen in Himalayan and Tibetan highlanders—and often misdiagnosed as a viral illness—as a result of recent rapid air, train, and motorable-road access to high-altitude settlements.

PHYSIOLOGY

Ascent to a high altitude subjects the body to a decrease in barometric pressure that results in a decreased partial pressure of oxygen in the inspired gas in the lungs. This change leads in turn to less pressure driving oxygen diffusion from the alveoli and throughout the oxygen cascade. A normal initial "struggle response" to such an ascent includes increased ventilation—the cornerstone of acclimatization—mediated by the carotid bodies. Hyperventilation may cause respiratory alkalosis and dehydration. Respiratory alkalosis may be extreme, with an arterial blood pH of >7.7 (e.g., at the summit of Everest). Alkalosis may depress the ventilatory drive during sleep, with consequent periodic breathing and hypoxemia. During early acclimatization, renal suppression of carbonic anhydrase and excretion of dilute alkaline urine combat alkalosis and tend to bring the pH of the blood to normal. Other physiologic changes during normal acclimatization include increased sympathetic tone; increased erythropoietin levels, leading to increased hemoglobin levels and red blood cell mass; increased tissue capillary density and mitochondrial numbers; and higher levels of 2,3-bisphosphoglycerate, enhancing oxygen utilization. Even with normal acclimatization, however, ascent to a high altitude decreases maximal exercise capacity (by ~1% for every 100 m gained above 1500 m) and increases susceptibility to cold injury due to peripheral vasoconstriction. If the ascent is made faster than the body can adapt to the stress of hypobaric hypoxemia, altitude-related disease states can result.

GENETICS

Hypoxia-inducible factor, which acts as a master switch in high-altitude adaptation, controls transcriptional responses to hypoxia throughout the body and is involved in the release of vascular endothelial growth factor (VEGF) in the brain, erythropoiesis, and other pulmonary and cardiac functions at high altitudes. In particular, the gene *EPAS1*, which codes for transcriptional regulator hypoxia-inducible factor 2α, appears to play an important role in the adaptation of Tibetans living at high altitude, resulting in lower hemoglobin concentrations than are found in Han Chinese or South American highlanders. Other genes implicated include *EGLN1* and *PPARA*, which are also associated with hemoglobin concentration. Some evidence indicates that these genetic changes occurred within the past 3000 years, which is very fast in evolutionary terms. An intriguing question is whether the Sherpas' well-known mountain-climbing ability is partially attributable to their Tibetan ancestry, with overrepresentation of variants of *EPAS*. A striking recent finding is that some of these genetic characteristics may stem from those of Denisovan hominids who were contemporaries of the Neanderthals.

For acute altitude illness, a single gene variant is unlikely to be found, but differences in the susceptibility of individuals and populations, familial clustering of cases, and a positive association of some genetic variants all clearly support a role for genetics. Approximately 58 candidate genes have been tested, and at least one variant from 17 of these genes is associated with altitude illness.

ACUTE MOUNTAIN SICKNESS AND HIGH-ALTITUDE CEREBRAL EDEMA

AMS is a neurologic syndrome characterized by nonspecific symptoms (headache, nausea, fatigue, and dizziness), with a paucity of physical findings, developing 6–12 h after ascent to a high altitude. AMS is a clinical diagnosis. For uniformity in research studies, the Lake Louise Scoring System, created at the 1991 International Hypoxia Symposium, is generally used. AMS must be distinguished from exhaustion, dehydration, hypothermia, alcoholic hangover, and hyponatremia. AMS and HACE are thought to represent opposite ends of a continuum of altitude-related neurologic disorders. HACE (but not AMS) is an encephalopathy whose hallmarks are ataxia and altered consciousness with diffuse cerebral involvement but generally without focal neurologic deficits. Progression to these signal manifestations can be rapid. Papilledema and, more commonly, retinal hemorrhages may develop. In fact, retinal hemorrhages occur frequently at ≥5000 m, even in individuals without clinical symptoms of AMS or HACE. It is unclear whether retinal hemorrhage and cerebral hemorrhage at high altitude are caused by the same mechanism.

Risk Factors The most important risk factors for the development of altitude illness are the rate of ascent and a prior history of high-altitude illness. Exertion is a risk factor, but lack of physical fitness is not. An attractive but still speculative hypothesis proposes that AMS develops in people who have inadequate cerebrospinal capacity to buffer the brain swelling that occurs at high altitude. Children and adults seem to be equally affected, but people >50 years of age may be less likely to develop AMS than younger people. Most studies reveal no gender difference in AMS incidence. One study showed that, in women, adaptive responses to hypoxia with aging are blunted by menopause but can be maintained with endurance training. Sleep desaturation—a common phenomenon at high altitude—is associated with AMS. Debilitating fatigue consistent with severe AMS on descent from a summit is an important risk factor for death in mountaineers. A prospective study involving trekkers and climbers who ascended to altitudes between 4000 m and 8848 m showed that high oxygen desaturation and low ventilatory response to hypoxia during exercise are independent predictors of severe altitude illness. However, because there may be a large overlap between groups of susceptible and nonsusceptible individuals, accurate cutoff values are hard to define. Prediction is made more difficult because the pretest probabilities of HAPE and HACE are low. Neck irradiation or surgery damaging the carotid bodies, respiratory tract infections, and dehydration appear to be other potential risk factors for altitude illness. Unless guided by clinical signs and symptoms, pulse oximeter readings alone on a trek should not be used to predict AMS.

Pathophysiology Hypobaric hypoxia is the main trigger for altitude illness. In established AMS, raised intracranial pressure, increased sympathetic activity, relative hypoventilation, fluid retention and redistribution, and impaired gas exchange have all been well noted; these factors may play an important role in the pathophysiology of AMS. Severe hypoxemia can lead to a greater than normal increase in cerebral blood flow.

FIGURE 453-1 T2 magnetic resonance image of the brain of a patient with high-altitude cerebral edema (HACE) shows marked swelling and a hyperintense posterior body and splenium of the corpus callosum (area with dense opacity). The patient, a climber, went on to climb Mount Everest about 9 months after this episode of HACE. *(With permission from Wilderness Environ Med 15:53–55, 2004.)*

However, the exact mechanisms underlying AMS and HACE are unknown. Evidence points to a central nervous system process. MRI studies have suggested that vasogenic (interstitial) cerebral edema is a component of the pathophysiology of HACE. In the setting of high-altitude illness, the MRI findings shown in Fig. 453-1 are confirmatory of HACE, with increased signal in the white matter and particularly in the splenium of the corpus callosum. In addition, hemosiderin deposits in the corpus callosum have been characterized as long-lasting footprints of HACE. Quantitative analysis in a 3-tesla MRI study revealed that hypoxia is associated with mild vasogenic cerebral edema irrespective of AMS. This finding is in keeping with case reports of suddenly symptomatic brain tumors and of cranial nerve palsies without AMS at high altitudes. Vasogenic edema may become cytotoxic (intracellular) in severe HACE.

Impaired cerebral autoregulation in the presence of hypoxic cerebral vasodilation and altered permeability of the blood–brain barrier due to hypoxia-induced chemical mediators like histamine, arachidonic acid, and VEGF may all contribute to brain edema. In 1995, VEGF was first proposed as a potent promoter of capillary leakage in the brain at high altitude, and studies in mice have borne out this role. Although studies of VEGF in climbers have yielded inconsistent results regarding its association with altitude illness, indirect evidence of a role for this growth factor in AMS and HACE comes from the observation that dexamethasone, when used in the prevention and treatment of these conditions, blocks hypoxic upregulation of VEGF. Other factors in the development of cerebral edema may be the release of calcium-mediated nitric oxide and neuronally mediated adenosine, which may promote cerebral vasodilation. Venous outflow obstruction resulting in increased brain capillary pressure is also thought to play an important role in the development of HACE. Lesions in the globus pallidum (which is sensitive to hypoxia) leading to Parkinson's disease have been reported to be complications of HACE.

The pathophysiology of the most common and prominent symptom of AMS—headache—remains unclear because the brain itself is an insensate organ; only the meninges contain trigeminal sensory nerve fibers. The cause of high-altitude headache is multifactorial. Various chemicals and mechanical factors activate a final common pathway, the trigeminovascular system. In the genesis of high-altitude headache, the response to nonsteroidal anti-inflammatory drugs and glucocorticoids provides indirect evidence for involvement of the arachidonic acid pathway and inflammation. Although high altitude may be a trigger for migraine, it is unclear whether high-altitude headache and migraine share the same pathophysiology.

TABLE 453-1 Management of Altitude Illness

CONDITION	MANAGEMENT
Acute mountain sickness (AMS), mild[a]	Discontinuation of ascent Treatment with acetazolamide (250 mg q12h) Descent[b]
AMS, moderate[a]	Immediate descent for worsening symptoms Use of low-flow oxygen if available Treatment with acetazolamide (250 mg q12h) and/or dexamethasone (4 mg q6h)[c] Hyperbaric therapy[d]
High-altitude cerebral edema (HACE)	Immediate descent or evacuation Administration of oxygen (2–4 L/min) Treatment with dexamethasone (8 mg PO/IM/IV; then 4 mg q6h) Hyperbaric therapy if descent is not possible
High-altitude pulmonary edema (HAPE)	Immediate descent or evacuation Minimization of exertion while patient is kept warm Administration of oxygen (4–6 L/min) to bring O_2 saturation to >90% Adjunctive therapy with nifedipine[e] (30 mg, extended-release, q12h) Hyperbaric therapy if descent is not possible

[a]Categorization of cases as mild or moderate is a subjective judgment based on the severity of headache and the presence and severity of other manifestations (nausea, fatigue, dizziness, insomnia). [b]No fixed altitude is specified; the patient should descend to a point below that at which symptoms developed. [c]Acetazolamide treats and dexamethasone masks symptoms. For prevention (as opposed to treatment) of AMS, 125–250 mg of acetazolamide q12h or (when acetazolamide is contraindicated—e.g., in people with sulfa allergy) 4 mg of dexamethasone q12h may be used. [d]In hyperbaric therapy (Fig. 453-2), the patient is placed in a portable altitude chamber or bag to simulate descent. [e]Nifedipine at this dose is also effective for the prevention of HAPE, as is salmeterol (125 mg inhaled twice daily), tadalafil (10 mg twice daily), or dexamethasone (8 mg twice daily).

Prevention and Treatment (Table 453-1) Gradual ascent, with adequate time for acclimatization, is the best method for the prevention of altitude illness. Even though there may be individual variation in the rate of acclimatization, a conservative approach would be a graded ascent of ≤300 m from the previous day's sleeping altitude above 3000 m, and taking every third day of gain in sleeping altitude as an extra day for acclimatization is helpful. Spending one night at an intermediate altitude before proceeding to a higher altitude may enhance acclimatization and attenuate the risk of AMS. Another protective factor in AMS is high-altitude exposure during the preceding 2 months; for example, the incidence and severity of AMS at 4300 m are reduced by 50% with an ascent after 1 week at an altitude ≥2000 m rather than with an ascent from sea level. Studies have examined whether exposure to a normobaric hypoxic environment (in a room or a tent) before an ascent can provide protection against AMS. In double-blind placebo-controlled trials, repeated intermittent exposure (60–90 min) to normobaric hypoxia (up to 4500 m) or continuous exposure to 3000 m during 8 h of sleep for 7 consecutive days failed to reduce the incidence of AMS at altitudes of 4300–4559 m. However, a recent study with 14 consecutive nights in a similar setting demonstrated reduced symptoms and incidence of AMS. More uniform studies need to be done to clarify the utility, if any, of this approach to preacclimatization.

Clearly, a flexible itinerary that permits additional rest days will be helpful. Sojourners to high-altitude locations must be aware of the symptoms of altitude illness and should be encouraged not to ascend further if these symptoms develop. Any hint of HAPE (see below) or HACE mandates descent. Proper hydration (but not overhydration) in high-altitude trekking and climbing, aimed at countering fluid loss due to hyperventilation and sweating, may play a role in avoiding AMS. Pharmacologic prophylaxis at the time of travel to high altitudes is warranted for people with a history of AMS or when a graded ascent and acclimatization are not possible—e.g., when rapid ascent is necessary for rescue purposes or when flight to a high-altitude location is required. Acetazolamide is the drug of choice for AMS prevention. It inhibits renal carbonic anhydrase, causing prompt bicarbonate diuresis

that leads to metabolic acidosis and hyperventilation. Acetazolamide (125–250 mg twice a day), administered for 1 day before ascent and continued for 2 or 3 days, is effective. Treatment can be restarted if symptoms return after discontinuation of the drug. Higher doses are not required. A meta-analysis limited to randomized controlled trials revealed that 125 mg of acetazolamide twice daily was effective in the prevention of AMS, with a relative-risk reduction of ~48% from values obtained with placebo. Paresthesia and a tingling sensation are common side effects of acetazolamide. This drug is a nonantibiotic sulfonamide that has low-level cross-reactivity with sulfa antibiotics; as a result, severe reactions are rare. Dexamethasone (8 mg/d in divided doses) is also effective. A large-scale, randomized, double-blind, placebo-controlled trial in partially acclimatized trekkers clearly showed that *Ginkgo biloba* is ineffective in the prevention of AMS. In randomized studies, ibuprofen (600 mg three times daily) has been shown to be beneficial in the prevention of AMS. Recently, acetaminophen (1 g three times daily) was as effective as ibuprofen at the above dosage in a randomized, double-blind study. However, more definitive studies and (for ibuprofen) a proper gastrointestinal-bleeding risk assessment need to be conducted before these drugs can be routinely recommended for AMS prevention. Many drugs, including spironolactone, medroxyprogesterone, magnesium, calcium channel blockers, and antacids, confer no benefit in the prevention of AMS. Starkly conflicting results from a number of trials of inhaled budesonide for the prevention of AMS have recently been published, but, in all likelihood, the drug is ineffective. Similarly, no efficacy studies are available for coca leaves (a weak form of cocaine), which are offered to high-altitude travelers in the Andes, or for *soroche* pills, which contain aspirin, caffeine, and acetaminophen and are sold over the counter in Bolivia and Peru. Finally, a word of caution applies in the pharmacologic prevention of altitude illness. A fast-growing population of climbers in pursuit of a summit are using prophylactic drugs such as glucocorticoids in an attempt to improve their performance; the outcome can be tragic because of potentially severe side effects of these drugs.

For the treatment of mild AMS, rest alone with analgesic use may be adequate. Descent and the use of acetazolamide and (if available) oxygen are sufficient to treat most cases of moderate AMS. Even a minor descent (400–500 m) may be adequate for symptom relief. For moderate AMS or early HACE, dexamethasone (4 mg orally or parenterally) is highly effective. For HACE, immediate descent is mandatory. When descent is not possible because of poor weather conditions or darkness, a simulation of descent in a portable hyperbaric chamber **(Fig. 453-2)** can be very effective. Pressurization in the bag for 1–2 h often leads to spectacular improvement and, like dexamethasone administration, "buys time." Thus, in certain high-altitude locations (e.g., remote pilgrimage sites), the decision to bring along the lightweight hyperbaric chamber may prove lifesaving. Like nifedipine, phosphodiesterase-5 inhibitors have no role in the treatment of AMS or HACE.

FIGURE 453-2 A hyperbaric bag. The cylindrical, portable (<7 kg) nylon bag has a one-way valve to prevent carbon dioxide buildup. A patient with severe acute mountain sickness (AMS), high-altitude cerebral edema (HACE), or high-altitude pulmonary edema (HAPE) is zipped inside the bag, which is continuously inflated with a foot pedal. The increased barometric pressure (2 psi) inside the bag simulates descent; for example, at 4250 m, the equivalent "elevation" inside the bag is ~2100 m. No supplemental oxygen is required.

HIGH-ALTITUDE PULMONARY EDEMA

Risk Factors and Manifestations Unlike HACE (a neurologic disorder), HAPE is primarily a pulmonary problem and therefore is not necessarily preceded by AMS. HAPE develops within 2–4 days after arrival at high altitude; it rarely occurs after more than 4 or 5 days at the same altitude, probably because of remodeling and adaptation that render the pulmonary vasculature less susceptible to the effects of hypoxia. A rapid rate of ascent, a history of HAPE, respiratory tract infections, and cold environmental temperatures are risk factors. Men are more susceptible than women. People with abnormalities of the cardiopulmonary circulation leading to pulmonary hypertension—e.g., a large patent foramen ovale, mitral stenosis, primary pulmonary hypertension, and unilateral absence of the pulmonary artery—may be at increased risk of HAPE, even at moderate altitudes. For example, patent foramen ovale is four times more common among HAPE-susceptible individuals than in the general population. Echocardiography is recommended when HAPE develops at relatively low altitudes (<3000 m) and whenever cardiopulmonary abnormalities predisposing to HAPE are suspected.

The initial manifestation of HAPE may be a reduction in exercise tolerance greater than that expected at the given altitude. Although a dry, persistent cough may presage HAPE and may be followed by the production of blood-tinged sputum, cough in the mountains is almost universal and the mechanism is poorly understood. Tachypnea and tachycardia, even at rest, are important markers as illness progresses. Crackles may be heard on auscultation but are not diagnostic. HAPE may be accompanied by signs of HACE. Patchy or localized opacities **(Fig. 453-3)** or streaky interstitial edema may be noted on chest radiography. In the past, HAPE was mistaken for pneumonia due to the cold or for heart failure due to hypoxia and exertion. Kerley B lines or a bat-wing appearance are not seen on radiography. Electrocardiography may reveal right ventricular strain or even hypertrophy. Hypoxemia and respiratory alkalosis are consistently present unless the patient is taking acetazolamide, in which case metabolic acidosis may supervene. Assessment of arterial blood gases is not necessary in the evaluation of HAPE; an oxygen saturation reading with a pulse oximeter is generally adequate. The existence of a subclinical form of HAPE has been suggested by an increased alveolar–arterial oxygen gradient in Everest climbers near the summit, but hard evidence correlating this abnormality with the development of clinically relevant HAPE is lacking. Comet-tail scoring—an ultrasound technique—has been used

FIGURE 453-3 Chest radiograph of a patient with high-altitude pulmonary edema shows opacity in the right middle and lower zones simulating pneumonic consolidation. The opacity cleared almost completely in 2 days with descent and supplemental oxygen.

for evaluation of extravascular lung water at high altitude; the results have been encouraging, and this technique may potentially prove useful in detecting HAPE (clinical or subclinical) and even in ascertaining whether the presence of extravascular lung water is a harbinger of HAPE in patients with AMS.

Pathophysiology HAPE is a noncardiogenic pulmonary edema with normal pulmonary artery wedge pressure. It is characterized by patchy pulmonary hypoxic vasoconstriction that leads to overperfusion in some areas. This abnormality leads in turn to increased pulmonary capillary pressure (>18 mmHg) and capillary "stress" failure. The exact mechanism for this hypoxic vasoconstriction is unknown. Endothelial dysfunction due to hypoxia may play a role by impairing the release of nitric oxide, an endothelium-derived vasodilator. At high altitude, HAPE-prone persons have reduced levels of exhaled nitric oxide. The effectiveness of phosphodiesterase-5 inhibitors in alleviating altitude-induced pulmonary hypertension, decreased exercise tolerance, and hypoxemia supports the role of nitric oxide in the pathogenesis of HAPE. One study demonstrated that prophylactic use of tadalafil, a phosphodiesterase-5 inhibitor, decreases the risk of HAPE by 65%. In contrast, the endothelium also synthesizes endothelin-1, a potent vasoconstrictor whose concentrations are higher than average in HAPE-prone mountaineers.

Exercise and cold lead to increased pulmonary intravascular pressure and may predispose to HAPE. In addition, hypoxia-triggered increases in sympathetic drive may lead to pulmonary venoconstriction and extravasation into the alveoli from the pulmonary capillaries. Consistent with this concept, phentolamine, which elicits α-adrenergic blockade, improves hemodynamics and oxygenation in HAPE more than do other vasodilators. The study of tadalafil cited above also investigated dexamethasone in the prevention of HAPE. Surprisingly, dexamethasone reduced the incidence of HAPE by 78%—a greater decrease than with tadalafil. Besides possibly increasing the availability of endothelial nitric oxide, dexamethasone may have altered the excessive sympathetic activity associated with HAPE: the heart rate of participants in the dexamethasone arm of the study was significantly lowered. Finally, people susceptible to HAPE also display enhanced sympathetic activity during short-term hypoxic breathing at low altitudes.

Because many patients with HAPE have fever, peripheral leukocytosis, and an increased erythrocyte sedimentation rate, inflammation has been considered an etiologic factor in HAPE. However, strong evidence suggests that inflammation in HAPE is an epiphenomenon rather than the primary cause. Nevertheless, inflammatory processes (e.g., those elicited by viral respiratory tract infections) do predispose persons to HAPE—even those who are constitutionally resistant to its development.

Another proposed mechanism for HAPE is impaired transepithelial clearance of sodium and water from the alveoli. β-Adrenergic agonists upregulate the clearance of alveolar fluid in animal models. In a double-blind, randomized, placebo-controlled study of HAPE-susceptible mountaineers, prophylactic inhalation of the β-adrenergic agonist salmeterol reduced the incidence of HAPE by 50%. Other effects of β agonists may also contribute to the prevention of HAPE, but these findings are in keeping with the concept that alveolar fluid clearance may play a pathogenic role in this illness.

Prevention and Treatment (Table 453-1) Allowing sufficient time for acclimatization by ascending gradually (as discussed above for AMS and HACE) is the best way to prevent HAPE. Sustained-release nifedipine (30 mg), given once or twice daily, prevents HAPE in people who must ascend rapidly or who have a history of HAPE. Other drugs for the prevention of HAPE are listed in Table 453-1 (footnote e). Although dexamethasone is listed for prevention, its adverse-effect profile requires close monitoring. Acetazolamide has been shown to blunt hypoxic pulmonary vasoconstriction in animal models, and this observation warrants further study in HAPE prevention. However, one large study failed to show a decrease in pulmonary vasoconstriction in partially acclimatized individuals given acetazolamide.

Early recognition is paramount in the treatment of HAPE, especially when it is not preceded by the AMS symptoms of headache and nausea. Fatigue and dyspnea at rest may be the only initial manifestations. Descent and the use of supplementary oxygen (aimed at bringing oxygen saturation to >90%) are the most effective therapeutic interventions. Exertion should be kept to a minimum, and the patient should be kept warm. Hyperbaric therapy (Fig. 453-2) in a portable altitude chamber may be lifesaving, especially if descent is not possible and oxygen is not available. Oral sustained-release nifedipine (30 mg once or twice daily) can be used as adjunctive therapy. Inhaled β agonists, which are safe and convenient to carry, are useful in the prevention of HAPE and may be effective in its treatment, although no trials have yet been carried out. Inhaled nitric oxide and expiratory positive airway pressure may also be useful therapeutic measures but may not be available in high-altitude settings. No studies have investigated phosphodiesterase-5 inhibitors in the treatment of HAPE, but reports have described their use in clinical practice. The mainstays of treatment remain descent and (if available) oxygen.

In AMS, if symptoms abate (with or without acetazolamide), the patient may reascend gradually to a higher altitude. Unlike that in acute respiratory distress syndrome (another noncardiogenic pulmonary edema), the architecture of the lung in HAPE is usually well-preserved, with rapid reversibility of abnormalities (Fig. 453-3). This fact has allowed some people with HAPE to reascend slowly after a few days of descent and rest. In HACE, reascent after a few days may not be advisable during the same trip.

OTHER HIGH-ALTITUDE PROBLEMS

Sleep Impairment The mechanisms underlying sleep problems, which are among the most common adverse reactions to high altitude, include increased periodic breathing; changes in sleep architecture, with increased time in lighter sleep stages; and changes in rapid eye movement sleep. Sojourners should be reassured that sleep quality improves with acclimatization. In cases where drugs do need to be used, acetazolamide (125 mg before bedtime) is especially useful because this agent decreases hypoxemic episodes and alleviates sleeping disruptions caused by excessive periodic breathing. Whether combining acetazolamide with temazepam or zolpidem is more effective than administering acetazolamide alone is unknown. In combinations, the doses of temazepam and zolpidem should not be increased by >10 mg at high altitudes. Limited evidence suggests that diazepam causes hypoventilation at high altitudes and therefore is contraindicated. For trekkers with obstructive sleep apnea who are using a continuous positive airway pressure (CPAP) machine, the addition of acetazolamide, which will decrease centrally mediated sleep apnea, may be helpful. There is evidence to show that obstructive sleep apnea at high altitude may decrease and "convert" to central sleep apnea.

Gastrointestinal Issues High-altitude exposure may be associated with increased gastric and duodenal bleeding, but further studies are required to determine whether there is a causal effect. Because of decreased atmospheric pressure and consequent intestinal gas expansion at high altitudes, many sojourners experience abdominal bloating and distension as well as excessive flatus expulsion. In the absence of diarrhea, these phenomena are normal, if sometimes uncomfortable. Accompanying diarrhea, however, may indicate the involvement of bacteria or *Giardia* parasites, which are common at many high-altitude locations in the developing world. Prompt treatment with fluids and empirical antibiotics may be required to combat dehydration in the mountains. Hemorrhoids are common on high-altitude treks; treatment includes hot soaks, application of hydrocortisone ointment, and measures to avoid constipation.

High-Altitude Cough High-altitude cough can be debilitating and is sometimes severe enough to cause rib fracture, especially at >5000 m. The etiology of this common problem is probably multifactorial. Although high-altitude cough has been attributed to inspiration of cold dry air, this explanation appears not to be sufficient by itself; in long-duration studies in hypobaric chambers, cough has occurred

despite controlled temperature and humidity. The implication is that hypoxia also plays a role. Exercise can precipitate cough at high altitudes, possibly because of water loss from the respiratory tract. Long-acting β agonists and glucocorticoids prevent bronchoconstriction that otherwise may be brought on by cold and exercise. In general, infection does not seem to be a common etiology. Anecdotal reports have described the efficacy of an inhaled combination of fluticasone and salmeterol in the treatment of high-altitude cough. Many trekkers find it useful to wear a balaclava to trap some moisture and heat. In most situations, cough resolves upon descent.

High-Altitude Neurologic Events Unrelated to "Altitude Illness" Transient ischemic attacks (TIAs) and strokes have been well described in high-altitude sojourners outside the setting of altitude sickness. However, these descriptions are not based on cause (hypoxia) and effect. In general, symptoms of AMS present gradually, whereas many of these neurologic events happen suddenly. The population that suffers strokes and TIAs at sea level is generally an older age group with other risk factors, whereas those so afflicted at high altitudes are generally younger and probably have fewer risk factors for atherosclerotic vascular disease. Other mechanisms (e.g., migraine, vasospasm, focal edema, hypocapneic vasoconstriction, hypoxia in the watershed zones of minimal cerebral blood flow, or cardiac right-to-left shunt) may be operative in TIAs and strokes at high altitude.

Subarachnoid hemorrhage, transient global amnesia, delirium, and cranial nerve palsies (e.g., lateral rectus palsy) occurring at high altitudes but outside the setting of altitude sickness have been well described. Syncope is common at moderately high altitudes, generally occurs shortly after ascent, usually resolves without descent, and appears to be a vasovagal event related to hypoxemia. Seizures occur rarely with HACE, but hypoxemia and hypocapnia, which are prevalent at high altitudes, are well-known triggers that may contribute to new or breakthrough seizures in predisposed individuals. Nevertheless, the consensus among experts is that sojourners with well-controlled seizure disorders can ascend to high altitudes.

Finally, persons with hypercoagulable conditions (e.g., antiphospholipid syndrome, protein C deficiency) who are asymptomatic at sea level may experience cerebral venous thrombosis (possibly due to enhanced blood viscosity triggered by polycythemia and dehydration) at high altitudes. Proper history taking, examination, and prompt investigations where possible will help define these conditions as entities separate from altitude sickness. Administration of oxygen (where available) and prompt descent are the cornerstones of treatment of most of these neurologic conditions.

Ocular Problems Ocular issues are common in sojourners to high altitudes. Hypoxemia induced by altitude leads to increased retinal blood flow, which can be visible as engorged retinal veins on ophthalmoscopic examination. Both high flow and hypoxemic vascular damage causing permeability have been implicated in a breakdown of the blood–retina barrier and the formation of retinal hemorrhages. Blot, dot, flame, and white-centered hemorrhages can be observed. These hemorrhages usually resolve spontaneously with descent, with only mild symptoms and no lasting visual damage in most healthy eyes. The exception is hemorrhage in the macular area. Macular hemorrhages can cause devastating initial visual loss, particularly if bilateral, and have been reported to cause permanently decreased vision in a few cases.

Stroke syndromes such as retinal vein occlusion, retinal artery occlusion, ischemic optic neuropathy, and cortical visual loss have all been reported. With unilateral vision loss, it is always important to check for a relative afferent pupillary defect. Increased hematocrit combined with dehydration may contribute to these maladies. Glaucomatous optic nerve damage may progress with hypoxemia of altitude. Acetazolamide is helpful both in combating the respiratory alkalosis that comes with increased ventilation at high altitude and in lowering the interocular pressure; its use should be considered in patients with stable controlled glaucoma. Macular degeneration and diabetic eye disease are not directly exacerbated by ascent to high altitude. Dry eye and solar damage to the cornea, known as "snow blindness," are common. Wearing of high-quality UV blocking sunglasses, even on cloudy days, and attention to protecting and supplementing the tear film with artificial tear drops can greatly improve comfort and vision. Although modern refractive surgeries, such as photorefractive keratectomy (PRK) and laser in situ keratomileusis (LASIK), are stable at high altitude, patients who have undergone radial keratotomy should be cautioned that hypoxemia to the cornea can lead to swelling that shifts the refraction during ascent.

Psychological/Psychiatric Problems Delirium characterized by a sudden change in mental status, a short attention span, disorganized thinking, and an agitated state during the period of confusion has been well described in mountain climbers and trekkers without a prior history. In addition, anxiety attacks, often triggered at night by excessive periodic breathing, are well documented. The contribution of hypoxia to these conditions is unknown. Expedition medical kits need to include antipsychotic injectable drugs to control psychosis in patients in remote high-altitude locations.

PREEXISTING MEDICAL ISSUES

Because travel to high altitudes is increasingly popular, common conditions such as hypertension, coronary artery disease, and diabetes are more frequently encountered among high-altitude sojourners. This situation is of particular concern for the millions of elderly pilgrims with medical problems who visit high-altitude sacred areas (e.g., in the Himalayas) each year. In recent years, high-altitude travel has attracted intrepid trekkers who are taking immunosuppressive medications (e.g., kidney transplant recipients or patients undergoing chemotherapy). Recommended vaccinations and other precautions (e.g., hand washing) may be especially important for this group. Although most of these medical conditions do not appear to influence susceptibility to altitude illness, they may be exacerbated by ascent to altitude, exertion in cold conditions, and hypoxemia. Advice regarding the advisability of high-altitude travel and the impact of high-altitude hypoxia on these preexisting conditions is becoming increasingly relevant, but there are no evidence-based guidelines. In addition, recommendations made for relatively low altitudes (~3000 m) may not hold true for higher altitudes (>4000 m), where hypoxic stress is greater. Personal risks and benefits must be clearly thought through before ascent.

Hypertension At high altitudes, enhanced sympathetic activity may lead to a transient rise in blood pressure. Occasionally, nonhypertensive, healthy, asymptomatic trekkers have pathologically high blood pressure at high altitude that rapidly normalizes without medicines on descent. Sojourners should continue to take their antihypertensive medications at high altitudes. Hypertensive patients are not more likely than others to develop altitude illness. Because the probable mechanism of high-altitude hypertension is α-adrenergic activity, anti-α-adrenergic drugs like prazosin have been suggested for symptomatic patients and those with labile hypertension. It is best to start taking the drug several weeks before the trip and to carry a sphygmomanometer if a trekker has labile hypertension. Sustained-release nifedipine may also be useful. A recent observational cohort study of 672 hypertensive and nonhypertensive trekkers in the Himalayas showed that most travelers, including those with well-controlled hypertension, can be reassured that their blood pressure will remain relatively stable at high altitude. Although blood pressure may be extremely elevated at high altitude in normotensive and hypertensive people, it is unlikely to cause symptoms.

Coronary Artery Disease Myocardial oxygen demand and maximal heart rate are reduced at high altitudes because the VO_2 max (maximal oxygen consumption) decreases with increasing altitude. This effect may explain why signs of cardiac ischemia or dysfunction usually are not seen in healthy persons at high altitudes. Asymptomatic, fit individuals with no risk factors need not undergo any tests for coronary artery disease before ascent. For persons with ischemic heart disease, previous myocardial infarction, angioplasty, and/or bypass surgery, an exercise treadmill test is indicated. A strongly positive treadmill test is a contraindication for high-altitude trips. Patients with poorly controlled arrhythmias should avoid high-altitude travel, but

patients with arrhythmias that are well controlled with antiarrhythmic medications do not seem to be at increased risk. Sudden cardiac deaths are not noted with a greater frequency in the Alps than at lower altitudes; although sudden cardiac deaths are encountered every trekking season in the higher Himalayan range, accurate documentation is lacking.

Asthma Although cold air and exercise may provoke acute bronchoconstriction, asthmatic patients usually have fewer problems at high than at low altitudes, possibly because of decreased allergen levels and increased circulating catecholamine levels. Nevertheless, asthmatic individuals should carry all their medications, including oral glucocorticoids, with proper instructions for use in case of an exacerbation. Severely asthmatic persons should be cautioned against ascending to high altitudes.

Pregnancy In general, low-risk pregnant women ascending to 3000 m are not at special risk except for the relative unavailability of medical care in many high-altitude locations, especially in developing countries. Despite the lack of firm data on this point, venturing higher than 3000 m to altitudes at which oxygen saturation drops steeply seems unadvisable for pregnant women.

Obesity Although living at a high altitude has been suggested as a means of controlling obesity, obesity has also been reported to be a risk factor for AMS, probably because nocturnal hypoxemia is more pronounced in obese individuals. Hypoxemia may also lead to greater pulmonary hypertension, thus possibly predisposing the trekker to HAPE.

Sickle Cell Disease High altitude is one of the rare environmental exposures that occasionally provokes a crisis in persons with the sickle cell trait. Even when traversing mountain passes as low as 2500 m, people with sickle cell disease have been known to have a vaso-occlusive crisis. Sickle cell disease needs to be considered when persons traveling to high altitudes become unwell and develop left-upper-quadrant pain. Patients with known sickle cell disease who need to travel to high altitudes should use supplemental oxygen and travel with caution. Thalassemia has not been known to cause problems at high altitude.

Diabetes Mellitus Trekking at high altitudes may enhance sugar uptake. Thus, high-altitude travel may not pose problems for persons with diabetes that is well controlled with oral hypoglycemic agents. An eye examination before travel may be useful. Patients taking insulin may require lower doses on trekking/climbing days than on rest days. Because of these variations, diabetic patients need to carry a reliable glucometer and use fast-acting insulin. Ready access to sweets is also essential. It is important for companions of diabetic trekkers to be fully aware of potential problems like hypoglycemia.

Chronic Lung Disease Depending on disease severity and access to medical care, preexisting lung disease may not always preclude high-altitude travel. A proper pretravel evaluation must be conducted. Supplemental oxygen may be required if the predicted PaO_2 for the altitude is <50–55 mmHg. Preexisting pulmonary hypertension may also need to be assessed in these patients. If the result is positive, patients should be discouraged from ascending to high altitudes; if such travel is necessary, treatment with sustained-release nifedipine (20 mg twice a day) should be considered. Small-scale studies have revealed that when patients with bullous disease reach ~5000 m, bullous expansion and pneumothorax are not noted. Compared with information on chronic obstructive pulmonary disease, fewer data exist about the safety of travel to high altitude for people with pulmonary fibrosis, but acute exacerbation of pulmonary fibrosis has been seen at high altitude. A handheld pulse oximeter can be useful to check for oxygen saturation.

Chronic Kidney Disease Patients with chronic kidney disease can tolerate short-term stays at high altitudes, but theoretical concern persists about progression to end-stage renal disease. Acetazolamide, the drug most commonly used for altitude sickness, should be avoided by anyone with preexisting metabolic acidosis, which can be exacerbated by this drug. In addition, the acetazolamide dosage should be adjusted when the glomerular filtration rate falls to <50 mL/min, and the drug should not be used at all if this value falls to <10 mL/min.

Cirrhosis Of patients with cirrhosis, 16% may have portopulmonary arterial hypertension and 32% may have hepatopulmonary syndrome; these conditions may be detrimental at high altitude as they may cause exaggerated hypoxemia. Thus, screening for these problems is important in cirrhotic patients planning a high-altitude trip. In addition, acetazolamide may be inadvisable in these patients as the drug may increase the risk of hepatic encephalopathy.

CHRONIC MOUNTAIN SICKNESS AND HIGH-ALTITUDE PULMONARY HYPERTENSION IN HIGHLANDERS

The largest populations of highlanders live in the South American Andes, the Tibetan Plateau, and parts of Ethiopia. Chronic mountain sickness (*Monge's disease*) is a disease in highlanders that is characterized by excessive erythrocytosis with moderate to severe pulmonary hypertension leading to cor pulmonale. This condition was originally described in South America and has also been documented in Colorado and in the Han Chinese population in Tibet; it is much less common in Tibetans or in Ethiopian highlanders. Migration to a low altitude results in the resolution of chronic mountain illness. Venesection and acetazolamide are helpful.

High-altitude pulmonary hypertension is also a subacute disease of long-term high-altitude residents. Unlike Monge's disease, this syndrome is characterized primarily by pulmonary hypertension (not erythrocytosis) leading to heart failure. Indian soldiers living at extreme altitudes for prolonged periods and Han Chinese infants born in Tibet have presented with the adult and infantile forms, respectively. High-altitude pulmonary hypertension bears a striking pathophysiologic resemblance to brisket disease in cattle. Descent to a lower altitude is curative.

454 Hypothermia and Peripheral Cold Injuries

Daniel F. Danzl

HYPOTHERMIA

Accidental hypothermia occurs when there is an unintentional drop in the body's core temperature below 35°C (95°F). At this temperature, many of the compensatory physiologic mechanisms that conserve heat begin to fail. *Primary accidental hypothermia* is a result of the direct exposure of a previously healthy individual to the cold. The mortality rate is much higher for patients who develop *secondary hypothermia* as a complication of a serious systemic disorder or injury.

CAUSES

Primary accidental hypothermia is geographically and seasonally pervasive. Although most cases occur in the winter months and in colder

TABLE 454-1 Risk Factors for Hypothermia

Age extremes	Endocrine-related
Elderly	Diabetes mellitus
Neonates	Hypoglycemia
Environmental exposure	Hypothyroidism
Occupational	Adrenal insufficiency
Sports-related	Hypopituitarism
Inadequate clothing	Neurologic
Immersion	Cerebrovascular accident
Toxicologic and pharmacologic	Hypothalamic disorders
Ethanol	Parkinson's disease
Phenothiazines	Spinal cord injury
Barbiturates	Multisystemic
Anesthetics	Trauma
Neuromuscular blockers	Sepsis
Antidepressants	Shock
Insufficient fuel	Hepatic or renal failure
Malnutrition	Carcinomatosis
Marasmus	Burns and exfoliative dermatologic disorders
Kwashiorkor	Immobility or debilitation

climates, this condition is surprisingly common in warmer regions as well. Multiple variables render individuals at the extremes of age—both the elderly and neonates—particularly vulnerable to hypothermia **(Table 454-1)**. The elderly have diminished thermal perception and are more susceptible to immobility, malnutrition, and systemic illnesses that interfere with heat generation or conservation. Dementia, psychiatric illness, and socioeconomic factors often compound these problems by impeding adequate measures to prevent hypothermia. Neonates have high rates of heat loss because of their increased surface-to-mass ratio and their lack of effective shivering and adaptive behavioral responses. At all ages, malnutrition can contribute to heat loss because of diminished subcutaneous fat and as a result of depleted energy stores used for thermogenesis.

Individuals whose occupations or hobbies entail extensive exposure to cold weather are at increased risk for hypothermia. Military history is replete with hypothermic tragedies. Hunters, sailors, skiers, and climbers also are at great risk of exposure, whether it involves injury, changes in weather, or lack of preparedness.

Ethanol causes vasodilation (which increases heat loss), reduces thermogenesis and gluconeogenesis, and may impair judgment or lead to obtundation. Phenothiazines, barbiturates, benzodiazepines, heterocyclic antidepressants, and other medications reduce centrally mediated vasoconstriction. Many hypothermic patients are admitted to intensive care because of drug overdose. Anesthetics can block shivering responses; their effects are compounded when patients are not insulated adequately in the operating or recovery units.

Several types of endocrine dysfunction can lead to hypothermia. Hypothyroidism—particularly when extreme, as in myxedema coma—reduces the metabolic rate and impairs thermogenesis and behavioral responses. Adrenal insufficiency and hypopituitarism also increase susceptibility to hypothermia. Hypoglycemia, most commonly caused by insulin or oral hypoglycemic drugs, is associated with hypothermia, in part because of neuroglycopenic effects on hypothalamic function. Increased osmolality and metabolic derangements associated with uremia, diabetic ketoacidosis, and lactic acidosis can lead to altered hypothalamic thermoregulation.

Neurologic injury from trauma, cerebrovascular accident, subarachnoid hemorrhage, and hypothalamic lesion increases susceptibility to hypothermia. Agenesis of the corpus callosum (*Shapiro's syndrome*) is one cause of episodic hypothermia; in this syndrome, profuse perspiration is followed by a rapid fall in temperature. Acute spinal cord injury disrupts the autonomic pathways that lead to shivering and prevents cold-induced reflex vasoconstrictive responses.

Hypothermia associated with sepsis is a poor prognostic sign. Hepatic failure causes decreased glycogen storage and gluconeogenesis as well as a diminished shivering response. In acute myocardial infarction associated with low cardiac output, hypothermia may be reversed after adequate resuscitation. With extensive burns, psoriasis, erythrodermas, and other skin diseases, increased peripheral-blood flow leads to excessive heat loss.

THERMOREGULATION

Heat loss occurs through five mechanisms: radiation (55–65% of heat loss), conduction (10–15% of heat loss, much increased in cold water), convection (increased in the wind), respiration, and evaporation; both of the latter two mechanisms are affected by the ambient temperature and the relative humidity.

The preoptic anterior hypothalamus normally orchestrates thermoregulation **(Chap. 15)**. The immediate defense of thermoneutrality is via the autonomic nervous system, whereas delayed control is mediated by the endocrine system. Autonomic nervous system responses include the release of norepinephrine, increased muscle tone, and shivering, leading to thermogenesis and an increase in the basal metabolic rate. Cutaneous cold thermoreception causes direct reflex vasoconstriction to conserve heat. Prolonged exposure to cold also stimulates the thyroid axis, leading to an increased metabolic rate.

CLINICAL PRESENTATION

In most cases of hypothermia, the history of exposure to environmental factors (e.g., prolonged exposure to the outdoors without adequate clothing) makes the diagnosis straightforward. In urban settings, however, the presentation is often more subtle, and other disease processes, toxin exposures, or psychiatric diagnoses should be considered. Predicting the core temperature based on the clinical presentation is very difficult.

After initial stimulation by hypothermia, there is progressive depression of all organ systems. The timing of the appearance of these clinical manifestations varies widely **(Table 454-2)**. Without knowing the core temperature, it can be difficult to interpret other vital signs. For example, tachycardia disproportionate to the core temperature suggests secondary hypothermia resulting from hypoglycemia, hypovolemia, or a toxin overdose. Because carbon dioxide production declines progressively, the respiratory rate should be low; persistent hyperventilation suggests a central nervous system (CNS) lesion or one of the organic acidoses. A markedly depressed level of consciousness in a patient with mild hypothermia raises suspicion of an overdose or CNS dysfunction due to infection or trauma.

Physical examination findings can also be altered by hypothermia. For instance, the assumption that areflexia is solely attributable to hypothermia can obscure and delay the diagnosis of a spinal cord lesion. Patients with hypothermia may be confused or combative; these symptoms abate more rapidly with rewarming than with chemical or physical restraint. A classic example of maladaptive behavior in patients with hypothermia is paradoxical undressing, which involves the inappropriate removal of clothing in response to a cold stress. The cold-induced ileus and abdominal rectus spasm can mimic or mask the presentation of an acute abdomen **(Chap. 12)**.

When a patient in hypothermic cardiac arrest is first discovered, cardiopulmonary resuscitation (CPR) is indicated unless (1) a do-not-resuscitate status is verified, (2) obviously lethal injuries are identified, or (3) the depression of a frozen chest wall is not possible. Continuous CPR is normally recommended and interruptions should be avoided. In the field, when the core temperature is below 28°C, intermittent CPR may be effective.

As the resuscitation proceeds, the prognosis is grave if there is evidence of widespread cell lysis, as reflected by potassium levels >10–12 mmol/L (10–12 meq/L). Other findings that may preclude continuing resuscitation include a core temperature <10–12°C (<50–54°F), a pH <6.5, and evidence of intravascular thrombosis with a fibrinogen value <0.5 g/L (<50 mg/dL). The decision to terminate resuscitation before rewarming the patient past 33°C (91°F) should be predicated on the type and severity of the precipitants of hypothermia. Survival

TABLE 454-2 Physiologic Changes Associated with Accidental Hypothermia

SEVERITY	BODY TEMPERATURE	CENTRAL NERVOUS SYSTEM	CARDIOVASCULAR	RESPIRATORY	RENAL AND ENDOCRINE	NEUROMUSCULAR
Mild	35°C (95°F)– 32.2°C (90°F)	Linear depression of cerebral metabolism; amnesia; apathy; dysarthria; impaired judgment; maladaptive behavior	Tachycardia, then progressive bradycardia; cardiac cycle prolongation; vasoconstriction; increase in cardiac output and blood pressure	Tachypnea, then progressive decrease in respiratory minute volume; declining oxygen consumption; bronchorrhea; bronchospasm	Diuresis; increase in catecholamines, adrenal steroids, triiodothyronine, and thyroxine; increase in metabolism with shivering	Increased preshivering muscle tone, then fatiguing
Moderate	<32.2°C (90°F)–28°C (82.4°F)	EEG abnormalities; progressive depression of level of consciousness; pupillary dilation; paradoxical undressing; hallucinations	Progressive decrease in pulse and cardiac output; increased atrial and ventricular arrhythmias; suggestive (J-wave) ECG changes	Hypoventilation; 50% decrease in carbon dioxide production per 8°C (17.6°F) drop in temperature; absence of protective airway reflexes	50% increase in renal blood flow; renal autoregulation intact; impaired insulin action	Hyporeflexia; diminishing shivering-induced thermogenesis; rigidity
Severe	<28°C (<82.4°F)	Loss of cerebrovascular autoregulation; decline in cerebral blood flow; coma; loss of ocular reflexes; progressive decrease in EEG abnormalities	Progressive decrease in blood pressure, heart rate, and cardiac output; reentrant dysrhythmias; maximal risk of ventricular fibrillation; asystole	Pulmonic congestion and edema; 75% decrease in oxygen consumption; apnea	Decrease in renal blood flow that parallels decrease in cardiac output; extreme oliguria; poikilothermia; 80% decrease in basal metabolism	No motion; decreased nerve-conduction velocity; peripheral areflexia; no corneal or oculocephalic reflexes

Abbreviations: ECG, electrocardiogram; EEG, electroencephalogram.

Source: Modified from DF Danzl, RS Pozos: N Engl J Med 331:1756, 1994.

has occurred with a cardiac arrest time over 7 h. There are no validated prognostic indicators for recovery from hypothermia. A history of asphyxia with secondary cooling is the most important negative predictor of survival.

DIAGNOSIS AND STABILIZATION

Hypothermia is confirmed by measurement of the core temperature, preferably at two sites. Rectal probes should be placed to a depth of 15 cm and not adjacent to cold feces. A simultaneous esophageal probe should be placed 24 cm below the larynx; it may read falsely high during heated inhalation therapy. Relying solely on infrared tympanic thermography is not advisable.

After a diagnosis of hypothermia is established, cardiac monitoring should be instituted, along with attempts to limit further heat loss. If the patient is in ventricular fibrillation, it is unclear at what core temperature ventricular defibrillation (2 J/kg) should first be attempted. One attempt below 30°C is warranted. Further defibrillation attempts should be deferred until some rewarming (1°–2°C) is achieved and ventricular fibrillation is coarser. Although cardiac pacing for hypothermic bradydysrhythmias is rarely indicated, the transthoracic technique is preferable.

Supplemental oxygenation is always warranted, since tissue oxygenation is affected adversely by the leftward shift of the oxyhemoglobin dissociation curve. Pulse oximetry may be unreliable in patients with vasoconstriction. If protective airway reflexes are absent, gentle endotracheal intubation should be performed. Adequate preoxygenation will prevent ventricular arrhythmias.

Insertion of a gastric tube prevents dilation secondary to decreased bowel motility. Indwelling bladder catheters facilitate monitoring of cold-induced diuresis. Dehydration is encountered commonly with chronic hypothermia, and most patients benefit from an intravenous or intraosseous bolus of crystalloid. Normal saline is preferable to lactated Ringer's solution, as the liver in hypothermic patients inefficiently metabolizes lactate. The placement of a pulmonary artery catheter can cause perforation of the less compliant pulmonary artery. Insertion of a central venous catheter deeply into the cold right atrium should be avoided since this procedure, similar to transvenous pacing, can precipitate arrhythmias.

Arterial blood gases should not be corrected for temperature (Chap. 51). An uncorrected pH of 7.42 and a Pco_2 of 40 mmHg reflect appropriate alveolar ventilation and acid-base balance at any core temperature. Acid-base imbalances should be corrected gradually, since the bicarbonate buffering system is inefficient. A common error is overzealous hyperventilation in the setting of depressed CO_2 production. When the Pco_2 decreases by 10 mmHg at 28°C (82°F), it doubles the pH increase of 0.08 that occurs at 37°C (99°F).

The severity of anemia may be underestimated because the hematocrit increases 2% for each 1°C drop in temperature. White blood cell sequestration and bone marrow suppression are common, potentially masking an infection. Although hypokalemia is more common in chronic hypothermia, hyperkalemia also occurs; the expected electrocardiographic changes can be obscured by hypothermia. Patients with renal insufficiency, metabolic acidoses, or rhabdomyolysis are at greatest risk for electrolyte disturbances.

Coagulopathies are common because cold inhibits the enzymatic reactions required for activation of the intrinsic cascade. In addition, thromboxane B_2 production by platelets is temperature dependent, and platelet function is impaired. The administration of platelets and fresh-frozen plasma is therefore not effective. The prothrombin or partial thromboplastin times or the international normalized ratio can be deceptively normal and contrast with the observed in vivo coagulopathy. This contradiction occurs because all coagulation tests are routinely performed at 37°C (99°F), and the enzymes are thus rewarmed.

REWARMING STRATEGIES

The key initial decision is whether to rewarm the patient passively or actively. *Passive external rewarming* simply involves covering and insulating the patient in a warm environment. With the head also covered, the rate of rewarming is usually 0.5°–2°C (1.10°–4.4°F) per hour. This technique is ideal for previously healthy patients who develop acute, mild primary accidental hypothermia. The patient must have sufficient glycogen to support endogenous thermogenesis.

The application of heat directly to the extremities of patients with chronic severe hypothermia should be avoided because it can induce peripheral vasodilation and precipitate core temperature "afterdrop," a response characterized by a continual decline in the core temperature after removal of the patient from the cold. Truncal heat application reduces the risk of afterdrop.

Active rewarming is necessary under the following circumstances: core temperature <32°C (<90°F) (*poikilothermia*), cardiovascular instability, age extremes, CNS dysfunction, hormone insufficiency, and suspicion of secondary hypothermia. *Active external rewarming* is best accomplished with forced-air heating blankets. Other options include devices that circulate water through external heat exchange pads,

radiant heat sources, and hot packs. Monitoring a patient with hypothermia in a heated tub is extremely difficult. Electric blankets should be avoided because vasoconstricted skin is easily burned.

There are numerous widely available options for *active core rewarming*. Airway rewarming with heated humidified oxygen (40°–45°C [104°–113°F]) via mask or endotracheal tube is a convenient option. Although airway rewarming provides less heat than do some other forms of active core rewarming, it eliminates respiratory heat loss and adds 1°–2°C (2.2°–4.4°F) to the overall rewarming rate. Crystalloids should be heated to 40°–42°C (104°–108°F), but the quantity of heat provided is significant only during massive volume resuscitation. The most efficient method for heating and delivering fluid or blood is with a countercurrent in-line heat exchanger. Heated irrigation of the gastrointestinal tract or bladder transfers minimal heat because of the limited available surface area. These methods should be reserved for patients in cardiac arrest and then used in combination with all available active rewarming techniques.

Closed thoracic lavage is far more efficient in severely hypothermic patients with cardiac arrest. The hemithoraxes are irrigated through two inserted large-bore thoracostomy tubes. Thoracostomy tubes should not be placed in the left chest of a spontaneously perfusing patient for purposes of rewarming. Peritoneal lavage with the dialysate at 40°–45°C (104°–113°F) efficiently transfers heat when delivered through two catheters with outflow suction. Like peritoneal dialysis, standard hemodialysis is especially useful for patients with electrolyte abnormalities, rhabdomyolysis, or toxin ingestion. Another option involves the central venous insertion of a rapid endovascular warming device.

Extracorporeal blood rewarming options **(Table 454-3)** should be considered in severely hypothermic patients, especially those with *primary accidental hypothermia*. Cardiopulmonary bypass should be considered in nonperfusing patients without documented contraindications to resuscitation. Circulatory support may be the only effective option in patients with completely frozen extremities or those with significant tissue destruction coupled with rhabdomyolysis. There is no evidence that extremely rapid rewarming improves survival in perfusing patients. The best strategy is usually a combination of passive, truncal active, and active core rewarming techniques.

TABLE 454-3 Options for Extracorporeal Blood Rewarming

EXTRACORPOREAL REWARMING TECHNIQUE	CONSIDERATIONS
Continuous venovenous (CVV) rewarming	Circuit: CV catheter to CV, dual-lumen CV, or peripheral catheter No oxygenator/circulatory support Flow rates 150–400 mL/min ROR 2°–3°C (4.4°–6.6°F)/h
Hemodialysis	Circuit: single- or dual-vessel cannulation Stabilizes electrolyte or toxicologic abnormalities Exchange cycle volumes 200–500 mL/min ROR 2°–3°C (4.4°– 6.6°F)/h
Continuous arteriovenous rewarming (CAVR)	Circuit: percutaneous 8.5-Fr femoral catheters Requires systolic blood pressure of 60 mmHg No perfusionist/pump/anticoagulation Flow rates 225–375 mL/min ROR 3°–4°C (6.6°–8.8°F)/h
Cardiopulmonary bypass (CPB)	Circuit: full circulatory support with pump and oxygenator Perfusate-temperature gradient (5°–10°C [41°–50°F]) Flow rates 2–7 L/min (average 3–4 L/min) ROR up to 9.5°C (20.9°F)/h
Extracorporeal membrane oxygenation (ECMO)	Decreased risk of post-rewarming cardiorespiratory failure

Abbreviations: CV, central venous; ROR, rate of rewarming.

TREATMENT

Hypothermia

When a patient is hypothermic, target organs and the cardiovascular system respond minimally to most medications. Generally, IV medications are withheld below 30°C (86°F). In contrast to antiarrhythmics, low-dose vasopressor medications may improve the intra-arrest rates of return of spontaneous circulation. Because of increased binding of drugs to proteins as well as impaired metabolism and excretion, either a lower dose or a longer interval between doses should be used to avoid toxicity. As an example, the administration of repeated doses of digoxin or insulin would be ineffective while the patient is hypothermic, and the residual drugs would be potentially toxic during rewarming.

Achieving a mean arterial pressure of at least 60 mmHg should be an early objective. If the hypotension does not respond to crystalloid/colloid infusion and rewarming, low-dose dopamine support (2–5 μg/kg per min) should be considered. Perfusion of the vasoconstricted cardiovascular system also may be improved with low-dose IV nitroglycerin.

Atrial arrhythmias should be monitored initially without intervention, as the ventricular response should be slow and, unless preexistent, most will convert spontaneously during rewarming. The role of prophylaxis and treatment of ventricular arrhythmias is problematic. Preexisting ventricular ectopy may be suppressed by hypothermia and reappear during rewarming. None of the class I agents has proved to be safe and efficacious. Initiating empirical therapy for adrenal insufficiency usually is not warranted unless the history suggests steroid dependence or hypoadrenalism or efforts to rewarm with standard therapy fail. The administration of parenteral levothyroxine to euthyroid patients with hypothermia, however, is potentially hazardous. Because laboratory results can be delayed and confounded by the presence of the sick euthyroid syndrome **(Chap. 375)**, historic clues or physical findings suggestive of hypothyroidism should be sought. When myxedema is the cause of hypothermia, the relaxation phase of the Achilles reflex is prolonged more than is the contraction phase.

Hypothermia obscures most of the symptoms and signs of infection, notably fever and leukocytosis. Shaking rigors from infection may be mistaken for shivering. Except in mild cases, extensive cultures and repeated physical examinations are essential. Unless an infectious source is identified, empirical antibiotic prophylaxis is most warranted in the elderly, neonates, and immunocompromised patients.

Preventive measures should be discussed with high-risk individuals, such as the elderly and people whose work frequently exposes them to extreme cold. The importance of layered clothing and headgear, adequate shelter, increased caloric intake, and the avoidance of ethanol should be emphasized, along with access to rescue services.

FROSTBITE

Peripheral cold injuries include both freezing and nonfreezing injuries to tissue. Tissue freezes quickly when in contact with thermal conductors such as metal and volatile solutions. Other predisposing factors include constrictive clothing or boots, immobility, and vasoconstrictive medications. Frostbite occurs when the tissue temperature drops below 0°C (32°F). Ice-crystal formation subsequently distorts and destroys the cellular architecture. Once the vascular endothelium is damaged, stasis progresses rapidly to microvascular thrombosis. After the tissue thaws, there is progressive dermal ischemia. The microvasculature begins to collapse, arteriovenous shunting increases tissue pressures, and edema forms. Finally, thrombosis, ischemia, and superficial necrosis appear. The development of mummification and demarcation may take weeks to months.

CLINICAL PRESENTATION

The initial presentation of frostbite can be deceptively benign. The symptoms always include a sensory deficiency affecting light touch, pain, or temperature perception. The acral areas and distal extremities

are the most common insensate areas. Some patients describe a clumsy or "chunk of wood" sensation in the extremity.

Deep frostbitten tissue can appear waxy, mottled, yellow, or violaceous-white. Favorable presenting signs include some warmth or sensation with normal color. The injury is often superficial if the subcutaneous tissue is pliable or if the dermis can be rolled over bony prominences.

Frostnip may precede frostbite. Frostnip is a nonfreezing cold injury resulting from intense vasoconstriction of exposed acral skin.

Clinically, frostbite is superficial or deep. Superficial frostbite does not entail tissue loss but rather causes only anesthesia and erythema. The appearance of vesiculation surrounded by edema and erythema implies deeper involvement **(Fig. 454-1)**. Hemorrhagic vesicles reflect a serious injury to the microvasculature and indicate severe frostbite. Damages in subcuticular, muscular, or osseous tissues may result in amputation. An alternative classification establishes grades based on the location of presenting cyanosis; that is Grade 1, absence of cyanosis; Grade 2, cyanosis on the distal phalanx; Grade 3, cyanosis up to the MP joint; and Grade 4 cyanosis proximal to the MP joint.

The two most common nonfreezing peripheral cold injuries are *chilblain* (*pernio*) and *immersion* (*trench*) *foot*. Chilblain results from neuronal and endothelial damage induced by repetitive exposure to damp cold above the freezing point. Young females, particularly those with a history of Raynaud's phenomenon, are at greatest risk. Persistent vasospasticity and vasculitis can cause erythema, mild edema, and pruritus. Eventually plaques, blue nodules, and ulcerations develop. These lesions typically involve the dorsa of the hands and feet. In contrast, immersion foot results from repetitive exposure to wet cold above the freezing point. The feet initially appear cyanotic, cold, and edematous.

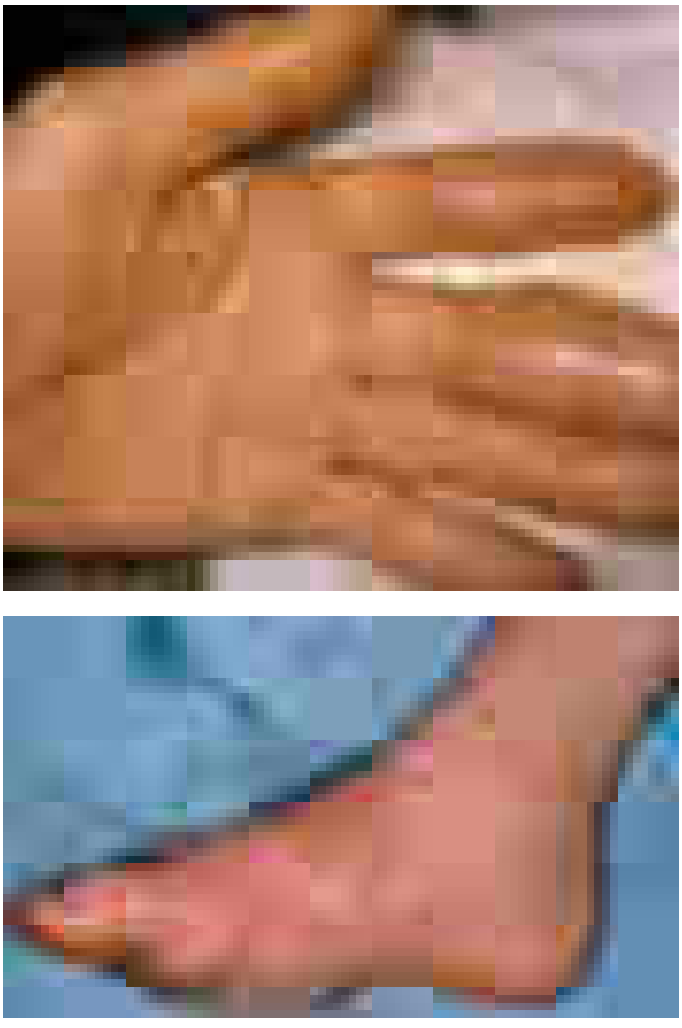

FIGURE 454-1 Frostbite with vesiculation, surrounded by edema and erythema.

The subsequent development of bullae is often indistinguishable from frostbite. This vesiculation rapidly progresses to ulceration and liquefaction gangrene. Patients with milder cases report hyperhidrosis, cold sensitivity, and painful ambulation for many years.

TREATMENT

Peripheral Cold Injuries

When frostbite accompanies hypothermia, hydration may improve vascular stasis. Frozen tissue should be thawed rapidly and completely by immersion in circulating water at 37°–40°C (99°–104°F) for 30–60 min. Rapid rewarming often produces an initial hyperemia. The early formation of large clear distal blebs is more favorable than that of smaller proximal dark hemorrhagic blebs. A common error is the premature termination of thawing, since the reestablishment of perfusion is intensely painful. Parenteral narcotics will be necessary with deep frostbite. If cyanosis persists after rewarming, the tissue compartment pressures should be monitored carefully.

Many antithrombotic and vasodilatory primary and adjunctive treatment regimens have been evaluated. The prostacyclin analogue iloprost given within 48 h after rewarming may prove useful. There is no conclusive evidence that sympathectomy, steroids, calcium channel blockers, or hyperbaric oxygen salvages tissue.

Patients who have deep frostbite injuries with the potential for significant morbidity should be considered for intravenous or intraarterial thrombolytic therapy. Angiography or pyrophosphate scanning may help evaluate the injury and monitor the progress of tissue plasminogen activator therapy (rt-PA). Heparin is recommended as adjunctive therapy. Intraarterial thrombolysis may reduce the need for digital and more proximal amputations when administered within 24 h of severe injuries. A treatment protocol for frostbite is summarized in **Table 454-4**.

Unless infection develops, any decision regarding debridement or amputation should generally be deferred. Angiography or

TABLE 454-4 Treatment for Frostbite

BEFORE THAWING	DURING THAWING	AFTER THAWING
Remove from environment.	Consider parenteral analgesia and ketorolac.	Gently dry and protect part; elevate; place pledgets between toes, if macerated.
Prevent partial thawing and refreezing.	Administer ibuprofen (400 mg PO).	If clear vesicles are intact, aspirate sterilely; if broken, debride and dress with antibiotic or sterile aloe vera ointment.
Stabilize core temperature and treat hypothermia.	Immerse part in 37°–40°C (99°–104°F) (thermometer-monitored) circulating water containing an antiseptic soap until distal flush (10–45 min).	Leave hemorrhagic vesicles intact to prevent desiccation and infection.
Protect frozen part—no friction or massage.	Encourage patient to gently move part.	Continue ibuprofen (400– 600 mg PO [12 mg/kg per day] q8 to 12h).
Address medical or surgical conditions.	If pain is refractory, reduce water temperature to 35°–37°C (95°–99°F) and administer parenteral narcotics.	Consider tetanus and streptococcal prophylaxis; elevate part. Administer hydrotherapy at 37°C (99°F). Consider dextran or phenoxybenzamine or, in severe cases, thrombolysis rt-PA (IV or intraarterial)

technetium-99 bone scan may assist in the determination of surgical margins. Magnetic resonance angiography may also demonstrate the line of demarcation earlier than does clinical demarcation.

The most common symptomatic sequelae reflect neuronal injury and persistently abnormal sympathetic tone, including paresthesias, thermal misperception, and hyperhidrosis. Delayed findings include nail deformities, cutaneous carcinomas, and epiphyseal damage in children.

Management of the chilblain syndrome is usually supportive. With refractory perniosis, alternatives include nifedipine, steroids, and limaprost, a prostaglandin E_1 analogue.

455 Heat-Related Illnesses

Daniel F. Danzl

Heat-related illnesses include a spectrum of disorders ranging from heat syncope, muscle cramps, and heat exhaustion to medical emergencies such as heatstroke. The core body temperature is normally maintained within a very narrow range. Although significant levels of hypothermia are tolerated **(Chap. 454)**, multiorgan dysfunction occurs rapidly at temperatures >41°–43°C. In contrast to heatstroke, the far more common sign of fever reflects intact thermoregulation.

THERMOREGULATION

Humans are capable of significant heat generation. Strenuous exercise can increase heat generation twentyfold. The heat load from metabolic heat production and environmental heat absorption is balanced by a variety of heat dissipation mechanisms. These central integrative dissipation pathways are orchestrated by the central thermostat, which is located in the preoptic nucleus of the anterior hypothalamus. Efferent signals sent via the autonomic nervous system trigger cutaneous vasodilation and diaphoresis to facilitate heat loss.

Normally, the body dissipates heat into the environment via four mechanisms. The *evaporation* of skin moisture is the single most efficient mechanism of heat loss but becomes progressively ineffective as the relative humidity rises to >70%. The *radiation* of infrared electromagnetic energy directly into the surrounding environment occurs continuously. (Conversely, radiation is a major source of heat gain in hot climates.) *Conduction*—the direct transfer of heat to a cooler object—and *convection*—the loss of heat to air currents—become ineffective when the environmental temperature exceeds the skin temperature.

Factors that interfere with the evaporation of diaphoresis significantly increase the risk of heat illness. Examples include dripping of sweat off the skin, constrictive or occlusive clothing, dehydration, and excessive humidity. While air is an effective insulator, the thermal conductivity of water is 25 times greater than that of air at the same temperature. The *wet-bulb globe temperature* is a commonly used index to assess the environmental heat load. This calculation considers the ambient air temperature, the relative humidity, and the degree of radiant heat.

The regulation of this heat load is complex and involves the central nervous system (CNS), thermosensors, and thermoregulatory effectors. The central thermostat activates the effectors that produce peripheral vasodilation and sweating. The skin surface is in effect the radiator and the principal location of heat loss, since skin blood flow can increase 25–30 times over the basal rate. This dramatic increase in skin blood flow, coupled with the maintenance of peripheral vasodilation, efficiently radiates heat. At the same time, there is a compensatory vasoconstriction of the splanchnic and renal beds.

Acclimatization to heat reflects a constellation of physiologic adaptations that permit the body to lose heat more efficiently. This process often requires one to several weeks of exposure and work in a hot environment. During acclimatization, the thermoregulatory set point is altered, and this alteration affects the onset, volume, and content of diaphoresis. The threshold for the initiation of sweating is lowered, and the amount of sweat increases, with a lowered salt concentration. Sweating rates can be 1–2 L/h in acclimated individuals during heat stress. Plasma volume expansion also occurs and improves cutaneous vascular flow. The heart rate lowers, with a higher stroke volume. After the individual leaves the hot environment, improved tolerance to heat stress dissipates rapidly, the plasma volume decreases, and de-acclimatization occurs within weeks.

PREDISPOSING FACTORS AND DIFFERENTIAL DIAGNOSIS

When there is an excessive heat load, unacclimated individuals can develop a variety of heat-related illnesses. Heat waves exacerbate the mortality rate, particularly among the elderly and among persons lacking adequate nutrition and access to air-conditioned environments. Secondary vascular events, including cerebrovascular accidents and myocardial infarctions, occur at least 10 times more often in conditions of extreme heat.

Exertional heat illness continues to occur when laborers, military personnel, or athletes exercise strenuously in the heat. A variety of common factors predispose to heat illness. In addition to the very young and very old, preadolescents and teenagers are at risk since they may use poor judgment when vigorously exercising in high humidity and heat. Other risk factors include obesity, poor conditioning and lack of acclimatization, and mild dehydration.

Cardiovascular inefficiency is a common feature of heat illness. Any physiologic or pharmacologic impediment to cutaneous perfusion will impair heat loss. Many patients are unaware of the heat risk associated with their medications. Anticholinergic agents impair sweating and blunt the normal cardiovascular response to heat. Phenothiazines and heterocyclic antidepressants also have anticholinergic properties that interfere with the function of the preoptic nucleus of the anterior hypothalamus due to central depletion of dopamine.

Calcium channel blockers, beta blockers, and various stimulants also inhibit sweating by reducing peripheral blood flow. To maintain the mean arterial blood pressure, increased cardiac output must be capable of compensating for progressive dehydration. A variety of stimulants and substances of abuse also increase muscle activity and heat production. Careful consideration of the differential diagnosis is important in the evaluation of a patient for a potential heat-related illness. The clinical setting may suggest other etiologies, such as malignant hyperthermia after general anesthesia. Neuroleptic malignant syndrome can be triggered by certain antipsychotic medications, including selective serotonin reuptake inhibitors. A variety of infectious and endocrine disorders as well as conditions with toxicologic or CNS etiologies may initially mimic heatstroke **(Table 455-1)**.

MINOR HEAT-EMERGENCY SYNDROMES

Heat edema is characterized by mild swelling of the hands, feet, and ankles during the first few days of significant heat exposure. The principal mechanism involves cutaneous vasodilation and pooling of interstitial fluid in response to heat stress. Heat also increases the secretion

TABLE 455-1 Heat-Related Illness: Predisposing Factors and Differential Diagnosis

ILLNESS	PREDISPOSING FACTORS
Cardiovascular inefficiency	Age extremes
	Beta/calcium channel blockade
	Congestive heart failure
	Dehydration
	Diuresis
	Obesity
	Poor physical fitness
Central nervous system illness	Cerebral hemorrhage
	Hypothalamic cerebrovascular accident
	Psychiatric disorders
	Status epilepticus
Impaired heat loss	Antihistamines
	Heterocyclic antidepressants
	Occlusive clothing
	Skin abnormalities
Endocrine-related illness	Diabetic ketoacidosis
	Pheochromocytoma
	Thyroid storm
Excessive heat load	Environmental conditions
	Exertion
	Fever
	Hypermetabolic state
	Lack of acclimatization
Infectious illness	Cerebral abscess
	Encephalitis
	Malaria
	Meningitis
	Sepsis syndrome
	Tetanus
	Typhoid
Toxicologic illness	Amphetamines
	Anticholinergic toxidrome
	Cocaine
	Dietary supplements
	Hallucinogens
	Malignant hyperthermia
	Neuroleptic malignant syndrome
	Salicylates
	Serotonin syndrome
	Strychnine
	Sympathomimetics
	Withdrawal syndromes (ethanol, hypnotics)

of antidiuretic hormone and aldosterone. Systemic causes of edema, including cirrhosis, nephrotic syndrome, and congestive heart failure, can usually be excluded by the history and physical examination. Heat edema generally resolves without treatment in several days. Simple leg elevation or thigh-high support hose will usually suffice. Diuretics are *not* effective and, in fact, predispose to volume depletion and the development of more serious heat-related illnesses.

Prickly heat (*miliaria rubra*, *lichen tropicus*) is a maculopapular, pruritic, erythematous rash that commonly occurs in clothed areas. Blockage of the sweat pores by debris from macerated stratum corneum causes inflammation in the sweat ducts. As the ducts dilate, they rupture and produce superficial vesicles. The predominant symptom is pruritus. In addition to antihistamines, chlorhexidine in a light cream or lotion provides some relief. In adults, localized areas may benefit from 1% salicylic acid TID, with caution taken to avoid salicylate intoxication. Clothing with breathable fabric should be clean and loose fitting, and activities or environments that induce diaphoresis should be avoided.

Heat syncope (exercise-associated collapse) can follow endurance exercise or occur in the elderly. Other common clinical scenarios include prolonged standing while stationary in the heat and sudden standing after prolonged exposure to heat. Heat stress routinely causes relative volume depletion, decreased vasomotor tone, and peripheral vasodilation. The cumulative effect of this decrease in venous return is postural hypotension, especially in nonacclimated elderly individuals. Many of those affected also have comorbidities. Therefore, other cardiovascular, neurologic, and metabolic causes of syncope should be considered. After removal from the heat source, most patients will recover promptly with cooling and rehydration.

Hyperventilation tetany occurs in some individuals when exposure to heat stimulates hyperventilation, producing respiratory alkalosis, paresthesias, and carpopedal spasm. Unlike heat cramps, heat tetany causes very little muscle-compartment pain. Treatment includes providing reassurance, moving the patient out of the heat, and addressing the hyperventilation.

HEAT CRAMPS

Heat cramps (exercise-associated muscle cramps) are intermittent, painful, and involuntary spasmodic contractions of skeletal muscles. They typically occur in an unacclimated individual who is at rest after vigorous exertion in a humid, hot environment. In contrast, cramps that occur in athletes during exercise last longer, are relieved by stretching and massage, and resolve spontaneously.

Of note, not all muscle cramps are related to exercise, and the differential diagnosis includes many other disorders. A variety of medications, myopathies, endocrine disorders, and sickle cell trait are other possible causes.

The typical patient with heat cramps is usually profusely diaphoretic and has been replacing fluid losses with copious water or other hypotonic fluids. Roofers, firefighters, military personnel, athletes, steel workers, and field workers are commonly affected. Other predisposing factors include insufficient sodium intake before intense activity in the heat and lack of heat acclimatization, resulting in sweat with a high salt concentration.

The precise pathogenesis of heat cramps appears to involve a relative deficiency of sodium, potassium, and fluid at the intracellular level. Coupled with copious hypotonic fluid ingestion, large amounts of sodium in the diaphoresis cause hyponatremia and hypochloremia, resulting in muscle cramps due to calcium-dependent muscle relaxation. Total-body depletion of potassium may be observed during the period of heat acclimatization. Rhabdomyolysis is very rare with routine exercise-associated muscle cramps.

Heat cramps that are not accompanied by significant dehydration can be treated with commercially available electrolyte solutions. Although the flavored electrolyte solutions are far more palatable, two 650-mg salt tablets dissolved in 1 quart of water produce a 0.1% saline solution. Individuals should avoid the ingestion of undissolved salt tablets, which are a gastric irritant and may induce vomiting.

HEAT EXHAUSTION

The physiologic hallmarks of heat exhaustion—in contrast to heatstroke—are the maintenance of thermoregulatory control and CNS function. The core temperature is usually elevated but is generally <40.5°C (<105°F). The two physiologic precipitants are water depletion and sodium depletion, which often occur in combination. Laborers, athletes, and elderly individuals exerting themselves in hot environments, without adequate fluid intake, tend to develop *water-depletion heat exhaustion*. Persons working in the heat frequently consume only two-thirds of their net water loss and are voluntarily dehydrated. In contrast, *salt-depletion heat exhaustion* occurs more slowly in unacclimated persons who have been consuming large quantities of hypotonic solutions.

Heat exhaustion is usually a diagnosis of exclusion because of the multitude of nonspecific symptoms. If any signs of heatstroke are present, rapid cooling and crystalloid resuscitation should be initiated immediately during stabilization and evaluation. Mild neurologic and gastrointestinal influenza-like symptoms are common. These symptoms may include headache, vertigo, ataxia, impaired judgment, malaise, dizziness,

nausea, and muscle cramps. Orthostatic hypotension and sinus tachycardia develop frequently. More significant CNS impairment suggests heatstroke or other infectious, neurologic, or toxicologic diagnoses.

Hemoconcentration does not always develop, and rapid infusion of isotonic IV fluids should be guided by frequent electrolyte determinations and perfusion requirements. Most cases of heat exhaustion reflect mixed sodium and water depletion. Sodium-depletion heat exhaustion is characterized by hyponatremia and hypochloremia. Hepatic aminotransferases are mildly elevated in both types of heat exhaustion. Urinary sodium and chloride concentrations are usually low.

Some patients with heat exhaustion develop heatstroke after removal from the heat-stress environment. Aggressive cooling of nonresponders is indicated until their core temperature is 39°C (102.2°F). Except in mild cases, free water deficits should be replaced slowly over 24–48 h to avoid a decrease of serum osmolality by >2 mOsm/h.

The disposition of younger, previously healthy heat-exhaustion patients who have no major laboratory abnormalities may include hospital observation and discharge after IV rehydration. Older patients with comorbidities (including cardiovascular disease) or predisposing factors often require inpatient fluid and electrolyte replacement, monitoring, and reassessment.

HEATSTROKE

The clinical manifestations of heatstroke reflect a total loss of thermoregulatory function. Typical vital-sign abnormalities include tachypnea, various tachycardias, hypotension, and a widened pulse pressure. Although there is no single specific diagnostic test, the historical and physical triad of exposure to a heat stress, CNS dysfunction, and a core temperature >40.5°C helps establish the preliminary diagnosis. Some patients with impending heat stroke will initially appear lucid. The definitive diagnosis should be reserved until the other potential causes of hyperthermia are excluded. Many of the usual laboratory abnormalities seen with heatstroke overlap with other conditions. If the patient's mental status does not improve with cooling, toxicologic screening may be indicated, and cranial CT and spinal fluid analysis can be considered.

The premonitory clinical characteristics may be nonspecific and include weakness, dizziness, disorientation, ataxia, and gastrointestinal or psychiatric symptoms. These prodromal symptoms often resemble heat exhaustion. The sudden onset of heatstroke occurs when the maintenance of adequate perfusion requires peripheral vasoconstriction to stabilize the mean arterial blood pressure. As a result, the cutaneous radiation of heat ceases. At this juncture, the core temperature rises dramatically. Since many patients with heatstroke also meet the criteria for systemic inflammatory response syndrome and have a broad differential diagnosis, rapid cooling is essential during the extensive diagnostic evaluation (Table 455-1).

There are two forms of heatstroke with significantly different manifestations **(Table 455-2)**. Classic (epidemic) heatstroke (CHS) usually occurs during long periods of high ambient temperature and humidity, as during summer heat waves. Patients with CHS commonly have chronic diseases that predispose to heat-related illness, and they may have limited access to oral fluids. Heat dissipation mechanisms are overwhelmed by both endogenous heat production and exogenous heat stress. Patients with CHS are often compliant with prescribed medications that can impair tolerance to a heat stress. In many of these dehydrated CHS patients, sweating has ceased and the skin is hot and dry.

TABLE 455-2 Typical Manifestations of Heatstroke

CLASSIC	EXERTIONAL
Older patient	Younger patient
Predisposing health factors/medications	Healthy condition
Epidemiology (heat waves)	Sporadic cases
Sedentary	Exercising
Anhidrosis (possible)	Diaphoresis (common)
Central nervous system dysfunction	Myocardial/hepatic injury
Oliguria	Acute renal failure
Coagulopathy (mild)	Disseminated intravascular coagulation
Mild lactic acidosis	Marked lactic acidosis
Mild creatine kinase elevation	Rhabdomyolysis
Normoglycemia/calcemia	Hypoglycemia/calcemia
Normokalemia	Hyperkalemia
Normonatremia	Hyponatremia

If cooling is delayed, severe hepatic dysfunction, renal failure, disseminated intravascular coagulation, and fulminant multisystem organ failure may occur. Hepatocytes are very heat sensitive. On presentation, the serum level of aspartate aminotransferase (AST) is routinely elevated. Eventually, levels of both AST and alanine aminotransferase (ALT) often increase to >100 times the normal values. Coagulation studies commonly demonstrate decreased platelets, fibrinogen, and prothrombin. Most patients with CHS require cautious crystalloid resuscitation, electrolyte monitoring, and—in certain refractory cases—consideration of central venous pressure (CVP) measurements. Hypernatremia is secondary to dehydration in CHS. Many patients exhibit significant stress leukocytosis, even in the absence of infection.

Patients with exertional heatstroke (EHS), in contrast to those with CHS, are often young and previously healthy, and their diagnosis is usually more obvious from the history. Athletes, laborers, and military recruits are common victims. Unlike those with CHS, many EHS patients present profusely diaphoretic despite significant dehydration. As a result of muscular exertion, rhabdomyolysis and acute renal failure are more common in EHS. Studies to detect rhabdomyolysis and its complications, including hypocalcemia and hyperphosphatemia, should be considered. Hyponatremia, hypoglycemia, and coagulopathies are frequent findings. Elevated creatine kinase and lactate dehydrogenase levels also suggest EHS. Oliguria is a common finding. Renal failure can result from direct thermal injury, untreated rhabdomyolysis, or volume depletion. Common urinalysis findings include microscopic hematuria, myoglobinuria, and granular or red cell casts.

With both CHS and EHS, heat-related reversible increases in cardiac biomarker levels are often present. Heatstroke often causes thermal cardiomyopathy. As a result, the CVP may be elevated despite significant dehydration. In addition, the patient often presents with potentially deceptive noncardiogenic pulmonary edema and basilar rales despite being significantly hypovolemic. The electrocardiogram commonly displays a variety of tachyarrhythmias, nonspecific ST-T wave changes, and heat-related ischemia or infarction. Rapid cooling—not the administration of antiarrhythmic medications—is essential.

Above 42°C (107.6°F), heat can rapidly produce direct cellular injury. Thermosensitive enzymes become nonfunctional, and eventually there is irreversible uncoupling of oxidative phosphorylation. The production of heat-shock proteins increases, and cytokines mediate a systemic inflammatory response. The vascular endothelium is also damaged, and this injury activates the coagulation cascade. Significant shunting away from the splanchnic circulation produces gastrointestinal ischemia. Endotoxins further impair normal thermoregulation. As a result, if cooling is delayed, severe hepatic dysfunction, permanent renal failure, disseminated intravascular coagulation, and fulminant multisystem organ failure may occur.

COOLING STRATEGIES

Before cooling is initiated, endotracheal intubation and continuous core-temperature monitoring should be considered. Peripheral methods to measure temperature are *not* reliable. Hypoglycemia is a frequent finding and can be addressed by glucose infusion. Since peripheral vasoconstriction delays heat dissipation, repeated administration of discrete boluses of isotonic crystalloid for hypotension is preferable to the administration of α-adrenergic agonists.

Evaporative cooling is frequently the most practical and effective technique. Rapid cooling is essential in both CHS and EHS, and an immediate improvement in vital signs and mental status may prove valuable for diagnostic purposes. Cool water (15°C [60°F]) is sprayed on the exposed skin while fans direct continuous airflow over the moistened skin. Cold packs applied to the neck, axillae, and groin are

useful cooling adjuncts. If cardiac electrodes will not adhere, they can be applied to the patient's back.

Immersion cooling in ice-cold water is an alternative option in EHS but can induce peripheral vasoconstriction and shivering. The initial increase in temperature from peripheral vasoconstriction will rapidly be overcome by the large conductive thermal transfer into cold water. This technique presents significant monitoring and resuscitation challenges in many clinical settings. The safety of immersion cooling is best established for young, previously healthy patients with EHS (but not for those with CHS). To avoid hypothermic afterdrop (continued cooling after immersion), active cooling should be terminated ~ 38°–39°C (100.4°F–102.2°F).

Cooling with commercially available cooling blankets should not be the sole technique used, since the rate of cooling is far too slow. Other methods are less efficacious and rarely indicated, such as IV infusion of cold fluids and cold irrigation of the bladder or gastrointestinal tract. Cold thoracic and peritoneal lavage are efficient maneuvers but are invasive and rarely necessary. Cardiopulmonary bypass provides effective cooling but is labor intensive and is rarely necessary.

RESUSCITATION

Aspiration commonly occurs in heatstroke, and endotracheal intubation is usually necessary. The metabolic demands are high, and supplemental oxygenation is essential due to hypoxemia induced by thermal stress and pulmonary dysfunction. The oxyhemoglobin dissociation curve is shifted to the right. Pneumonitis, pulmonary infarction, hemorrhage, edema, and acute respiratory distress syndrome occur frequently in heatstroke patients. Seizures are common, and can occur during therapeutic cooling. Cold induced tonic-clonic muscular rigidity mimics seizure activity.

The circulatory fluid requirements, particularly in CHS, may be deceptively modest. Aggressive cooling and modest volume repletion usually elevate the CVP to 12–14 mmHg. The reading, however, may be deceptive. Many patients present with a thermally induced hyperdynamic circulation accompanied by a high cardiac index, low peripheral vascular resistance, and an elevated CVP caused by right-sided heart failure. In contrast, most patients with EHS require far more zealous isotonic crystalloid resuscitation.

The hypotension that is initially common among patients with heatstroke results from both dehydration and high-output cardiac failure caused by peripheral vasodilation. Inotropes causing α-adrenergic stimulation (e.g., norepinephrine) can impede cooling by causing significant vasoconstriction. Vasoactive catecholamines such as dopamine or dobutamine may be necessary if the cardiac output remains depressed despite an elevated CVP, particularly in patients with a hyperdynamic circulation.

A wide variety of tachyarrhythmias are routinely observed on presentation and usually resolve spontaneously during cooling. The administration of atrial or ventricular antiarrhythmic medications is rarely indicated during cooling. Anticholinergic medications (including atropine) inhibit sweating and should be avoided. With a cardiac rhythm that sustains perfusion, electrical cardioversion of the hyperthermic myocardium should be deferred until the myocardium is cooled. Significant shivering, discomfort, or extreme agitation is preferably mitigated with short-acting benzodiazepines, which are ideal due to their renal clearance. On the other hand, chlorpromazine may lower the seizure threshold, has anticholinergic properties, and can exacerbate the hypotension or cause neuroleptic malignant syndrome. With hepatic dysfunction, barbiturates should be avoided and seizures treated with benzodiazepines.

Coagulopathies more commonly occur after the first day of illness. After cooling, the patient should be monitored for disseminated intravascular coagulation, and replacement therapy with fresh-frozen plasma and platelets should be considered.

There is no therapeutic role for antipyretics in the control of environmentally induced hyperthermia; these drugs block the actions of pyrogens at hypothalamic receptor sites. Salicylates can further uncouple oxidative phosphorylation in heatstroke and exacerbate coagulopathies. Acetaminophen may further stress hepatic function. The safety and efficacy of dantrolene is not established. Although aminocaproic acid impedes fibrinolysis, it may cause rhabdomyolysis and is not recommended in heatstroke.

DISPOSITION

Most patients with minor heat-emergency syndromes (including heat edema, heat syncope, and heat cramps) require only stabilization and treatment with outpatient follow-up. Although there are no decision rules to guide disposition choices in heat exhaustion, many of these patients have multiple predisposing factors and comorbidities that will require prolonged observation or hospital admission.

Essentially all patients with actual heatstroke require admission to a monitored setting, and most require intensive care. Many of these patients also require prolonged tracheal intubation, invasive hemodynamic monitoring, and support for various degrees of multiorgan dysfunction syndrome. The prognosis worsens if the initial core temperature exceeds 42°C (107.6°F) or if there was a prolonged period during which the core temperature exceeded this level. Other features of a negative prognosis include acute renal failure, massively elevated liver enzymes, and significant hyperkalemia. As expected, the number of dysfunctional organ systems also correlates directly with mortality risk.

456 Principles of Human Genetics

J. Larry Jameson, Peter Kopp

IMPACT OF GENETICS AND GENOMICS ON MEDICAL PRACTICE

Human genetics refers to the study of individual genes, their role and function in disease, and their mode of inheritance. Genomics refers to an organism's entire genetic information, the *genome*, and the function and interaction of DNA within the genome, as well as with environmental or nongenetic factors, such as a person's lifestyle. With the characterization of the human genome, genomics not only complements traditional genetics in our efforts to elucidate the etiology and pathogenesis of disease, but it plays an increasingly prominent role in diagnostics, prevention, and therapy **(Chap. 457)**. These transformative developments, emerging from the Human Genome Project, have been variably designated *genomic medicine*, *personalized medicine*, or *precision medicine*. Precision medicine aims at customizing medical decisions to an individual patient. For example, a patient's genetic characteristics (genotype) can be used to optimize drug therapy and predict efficacy, adverse events, and drug dosing of selected medications (*pharmacogenomics*) **(Chap. 64)**. The characterization of the mutational profile of a malignancy allows to identify driver mutations or overexpressed signaling molecules, which then facilitates the selection of targeted therapies. Genomic risk prediction models for common diseases are also beginning to emerge.

Genetics has traditionally been viewed through the window of relatively rare single-gene diseases. These disorders account for ~10% of pediatric admissions and childhood mortality. Historically, genetics has focused predominantly on chromosomal and metabolic disorders, reflecting the long-standing availability of techniques to diagnose these conditions. For example, conditions such as trisomy 21 (Down's syndrome) or monosomy X (Turner's syndrome) can be diagnosed using cytogenetics. Likewise, many metabolic disorders (e.g., phenylketonuria, familial hypercholesterolemia) are diagnosed using biochemical analyses. The advances in DNA diagnostics have extended the field of genetics to include virtually all medical specialties and have led to the elucidation of the pathogenesis of numerous monogenic disorders. In addition, it is apparent that virtually every medical condition has a genetic component. As is often evident from a patient's family history, many common disorders such as hypertension, heart disease, asthma, diabetes mellitus, and mental illnesses are significantly influenced by the genetic background. These polygenic or multifactorial (complex) disorders involve the contributions of many different genes, as well as environmental factors that can modify disease risk. Genome-wide association studies (GWAS) have elucidated numerous disease-associated loci and are providing novel insights into the allelic architecture of complex traits. These studies have been facilitated by the availability of comprehensive catalogues of human single-nucleotide polymorphism (SNP) haplotypes (HapMap, International Genome Sample Resource/1000 genomes project). Next-generation DNA sequencing (NGS) technologies have evolved rapidly and the cost of sequencing whole exomes (the exons within the genome, WES) or genomes (WGS) has plummeted. Comprehensive unbiased sequence analyses are now frequently used to characterize individuals with complex undiagnosed conditions or to determine the mutational profile of advanced malignancies in order to select better targeted therapies.

Cancer has a genetic basis because it results from acquired somatic mutations in genes controlling growth, apoptosis, and cellular differentiation **(Chap. 67)**. In addition, the development of many cancers is associated with a hereditary predisposition. Characterization of the genome (and epigenome) in various malignancies has led to fundamental new insights into cancer biology and reveals that the genomic profile of mutations is in many cases more important in determining the appropriate therapy than the organ in which the tumor originates. The Cancer Genome Atlas (TCGA) initiative of the National Cancer Institute and the National Human Genome Research Institute has already characterized the genomic landscape of >30 malignancies and several others will be completed in the near future. TCGA consists of comprehensive analyses of genomic and proteomic alterations and is providing fundamental new insights into the molecular pathogenesis of cancer. This knowledge has direct clinical ramifications as it impacts cancer taxonomy and the development of targeted therapies.

Genetic and genomic approaches have proven invaluable for the detection of infectious pathogens and are used clinically to identify agents that are difficult to culture such as mycobacteria, viruses, and parasites, or to track infectious agents locally or globally. In many cases, molecular genetics has improved the feasibility and accuracy of diagnostic testing and is beginning to open new avenues for therapy, including gene and cellular therapies **(Chap. 458)**. Molecular genetics has also provided the opportunity to characterize the *microbiome*, a new field that characterizes the population dynamics of bacteria, viruses, and parasites that coexist with humans and other animals **(Chap. 459)**. Emerging data indicate that the microbiome has significant effects on normal physiology as well as various disease states and the field is now focusing on defining the mechanisms underlying these interactions.

Molecular biology has significantly changed the treatment of human disease. Peptide hormones, growth factors, cytokines, and vaccines can now be produced in large amounts using recombinant DNA technology. Targeted modifications of these peptides provide the practitioner with improved therapeutic tools, as illustrated by genetically modified insulin analogues with more favorable kinetics. Lastly, there is reason to believe that a better understanding of the genetic basis of human disease will also have an increasing impact on disease prevention.

The astounding rate at which new genetic and genomic information is being generated creates a major challenge for physicians, health care providers, and basic investigators. Although many functional aspects of the genome remain unknown, there are many clinical situations where sufficient evidence exists for the use of genetic and genomic information to optimize patient care and treatment. Much genetic information resides in databases that provide easy access to the expanding information about the human genome, genetic disease, and genetic testing **(Table 456-1)**. For example, several thousand monogenic disorders are summarized in a large, continuously evolving compendium, referred to as the *Online Mendelian Inheritance in Man* (OMIM) catalogue (Table 456-1). The constant refinement of bioinformatics and new developments in *big data analytics*, together with the widespread adoption of electronic health records (EHRs), is simplifying the access, analysis and integration of this daunting amount of new information. Importantly, genomic data can be integrated readily into EHRs, and will accelerate the impact on clinical practice.

THE HUMAN GENOME

Structure of the Human Genome The Human Genome Project was initiated in the mid-1980s as an ambitious effort to characterize the entire human genome and culminated in the completion of the DNA sequence for the last of the human chromosomes in 2006. The scope of a whole genome sequence analysis can be illustrated by the following analogy. Human DNA consists of ~3 billion base pairs (bp) of DNA per haploid genome, which is nearly 1000-fold greater than that of the *Escherichia coli* genome. If the human DNA sequence were printed out, it would correspond to about 120 volumes of *Harrison's Principles of Internal Medicine*.

In addition to the human genome, the genomes of numerous organisms have been sequenced completely (~4000) or partially (~10,000) (Genomes Online Database [GOLD]; Table 456-1). They include, among

others, eukaryotes such as the mouse (*Mus musculus*), *Saccharomyces cerevisiae*, *Caenorhabditis elegans*, and *Drosophila melanogaster*; bacteria (e.g., *E. coli*); and archaea, viruses, organelles (mitochondria, chloroplasts), and plants (e.g., *Arabidopsis thaliana*). Genomic information of infectious agents has significant impact for the characterization of infectious outbreaks and epidemics. Other ramifications arising from the availability of genomic data include, among others, (1) the comparison of entire genomes (*comparative genomics*), (2) the study of large-scale expression of RNAs (*functional genomics*) and proteins (*proteomics*) to detect differences between various tissues in health and disease, (3) the characterization of the variation among individuals by establishing catalogues of sequence variations and SNPs, and (4) the identification of genes that play critical roles in the development of polygenic and multifactorial disorders.

CHROMOSOMES The human genome is divided into 23 different chromosomes, including 22 autosomes (numbered 1–22) and the X and Y sex chromosomes **(Fig. 456-1)**. Adult cells are *diploid*, meaning they contain two homologous sets of 22 autosomes and a pair of sex chromosomes. Females have two X chromosomes (XX), whereas males have one X and one Y chromosome (XY). As a consequence of meiosis, germ cells (sperm or oocytes) are haploid and contain one set of 22 autosomes and one of the sex chromosomes. At the time of fertilization, the diploid genome is reconstituted by pairing of the homologous chromosomes from the mother and father. With each cell division (mitosis), chromosomes are replicated, paired, segregated, and divided into two daughter cells.

STRUCTURE OF DNA DNA is a double-stranded helix composed of four different bases: adenine (A), thymidine (T), guanine (G), and cytosine (C). Adenine is paired to thymidine, and guanine is paired to cytosine, by hydrogen bond interactions that span the double helix (Fig. 456-1). DNA has several remarkable features that make it ideal for the transmission of genetic information. It is relatively stable, and the double-stranded nature of DNA and its feature of strict base-pair complementarity permit faithful replication during cell division. Complementarity also allows the transmission of genetic information from DNA → RNA → protein **(Fig. 456-2)**. mRNA is encoded by the so-called sense or coding strand of the DNA double helix and is translated into proteins by ribosomes.

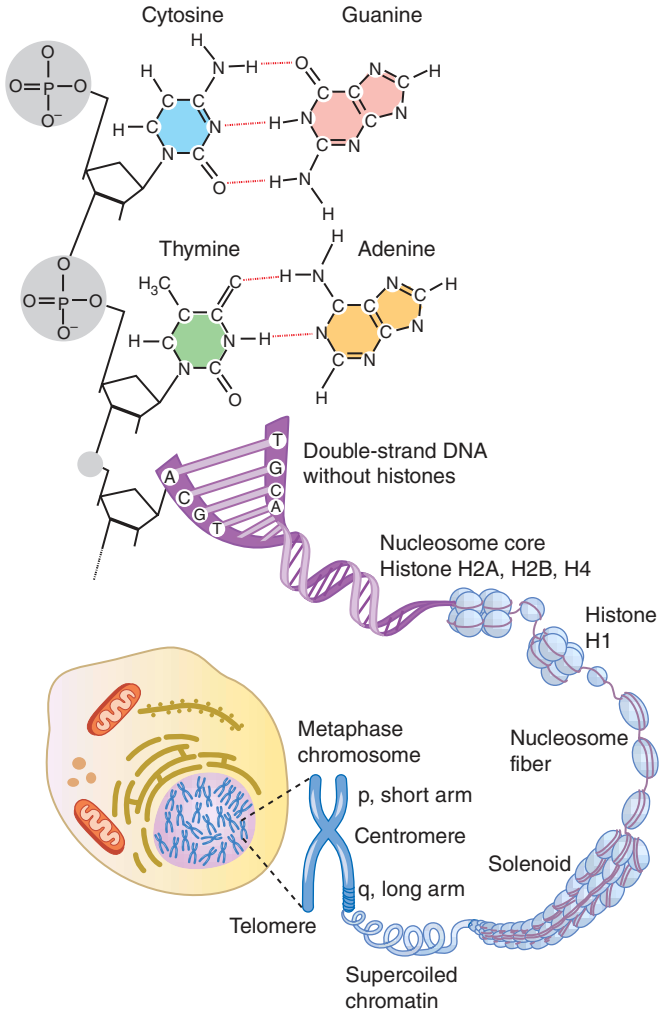

FIGURE 456-1 Structure of chromatin and chromosomes. Chromatin is composed of double-strand DNA that is wrapped around histone and nonhistone proteins forming nucleosomes. The nucleosomes are further organized into solenoid structures. Chromosomes assume their characteristic structure, with short (p) and long (q) arms at the metaphase stage of the cell cycle.

The presence of four different bases provides surprising genetic diversity. In the protein-coding regions of genes, the DNA bases are arranged into codons, a triplet of bases that specifies a particular amino acid. It is possible to arrange the four bases into 64 different triplet codons (4^3). Each codon specifies 1 of the 20 different amino acids, or a regulatory signal such as initiation and stop of translation. Because there are more codons than amino acids, the genetic code is degenerate; that is, most amino acids can be specified by several different codons. By arranging the codons in different combinations and in various lengths, it is possible to generate the tremendous diversity of primary protein structure.

DNA length is normally measured in units of 1000 bp (kilobases, kb) or 1,000,000 bp (megabases, Mb). Not all DNA encodes genes. In fact, genes account for only ~10–15% of DNA. Much of the remaining DNA consists of sequences, often of highly repetitive nature, the function of which remains incompletely understood. These repetitive DNA regions, along with nonrepetitive sequences that do not encode genes, serve, in part, a structural role in the packaging of DNA into chromatin (i.e., DNA bound to histone proteins, and chromosomes) and exert regulatory functions (Fig. 456-1).

GENES A *gene* is a functional unit that is regulated by transcription (see below) and encodes an RNA product, which is most commonly, but not always, translated into a protein that exerts activity within or outside the cell **(Fig. 456-3)**. Historically, genes were identified because they conferred specific traits that are transmitted from one generation to the next. Increasingly, they are characterized based on expression in various tissues (*transcriptome*). The size of genes is quite broad; some genes are only a few hundred base pairs, whereas others are extraordinarily large (2 Mb). The number of genes greatly underestimates the complexity of genetic expression, because single genes can generate multiple spliced messenger RNA (mRNA) products (*isoforms*), which are translated into proteins that are subject to complex posttranslational modification such as phosphorylation. *Exons* refer to the portion of genes that are eventually spliced together to form mRNA. *Introns* refer to the spacing regions between the exons that are spliced out of precursor RNAs during RNA processing. The gene locus also includes regions that are necessary to control its expression (Fig. 456-2). Current estimates predict roughly 20,000 protein-coding genes in the human genome with an average of about four different coding transcripts per gene. Remarkably, the exome only constitutes 1.14% of the genome. Of note, the number of transcripts is close to 200,000 and includes thousands of noncoding transcripts (RNAs of various length such as microRNAs [miRNA] and long noncoding RNAs [lncRNA]). These non-coding RNAs are involved in numerous cellular processes such as transcriptional and posttranscriptional regulation of gene expression, chromatin remodeling, and protein trafficking, among others. Not surprisingly, aberrant expression and/or mutations in these RNAs play a pathogenic role in numerous diseases.

SINGLE-NUCLEOTIDE POLYMORPHISMS Each individual has roughly 5 million sequence variants that differentiate one person from another. Some of these variants have no impact on health, whereas others may increase or lower the risk for developing a specific disease. Remarkably, however, the primary DNA sequence of humans has ~99.9% similarity compared to that of any other human. A SNP is a variation of a single base pair in the DNA. The identification of the ~10 million SNPs estimated to occur in the human genome has generated a catalogue of common genetic variants that occur in human beings from distinct ethnic backgrounds **(**Fig. 456-3). SNPs are the most common type of sequence variation and account for ~90% of all sequence variation. They occur on average every 100–300 bases and are the major source of genetic heterogeneity. SNPs that are in close proximity are inherited together (e.g., they are linked) and are referred to as *haplotypes* **(Fig. 456-4)**. Haplotype maps describe the nature and location of these SNP haplotypes and how they are distributed among individuals within and among populations, information that is facilitating GWAS designed to elucidate the complex interactions among multiple genes and lifestyle factors in multifactorial disorders (see below). Moreover, haplotype analyses are useful to assess variations in responses to medications (*pharmacogenomics*) and environmental factors, as well as the prediction of disease predisposition.

COPY NUMBER VARIATIONS Copy number variations (CNVs) are relatively large genomic regions (1 kb to several Mb) that have been duplicated or deleted on certain chromosomes and hence alter the diploid status of the DNA **(Fig. 456-5)**. It has been estimated that 5–10% of the genome can display CNVs. When comparing the genomes of two individuals, ~0.4–0.8% of their genomes differ in terms of CNVs scattered throughout the genome. Of note, de novo CNVs have been observed between monozygotic twins, who otherwise have identical genomes. Some CNVs have no functional consequences, whereas others have been associated with susceptibility or resistance to disease, and CNVs also occur in cancer cells.

Replication of DNA and Mitosis

Genetic information in DNA is transmitted to daughter cells under two different circumstances: (1) somatic cells divide by *mitosis*, allowing the diploid ($2n$) genome to replicate itself completely in conjunction with cell division; and (2) germ cells (sperm and ova) undergo *meiosis*, a process that enables the reduction of the diploid ($2n$) set of chromosomes to the haploid state ($1n$).

Prior to mitosis, cells exit the resting, or G_0 state, and enter the cell cycle. After traversing a critical checkpoint in G_1, cells undergo DNA synthesis (S phase), during which the DNA in each chromosome is replicated, yielding two pairs of sister chromatids ($2n \rightarrow 4n$). The process

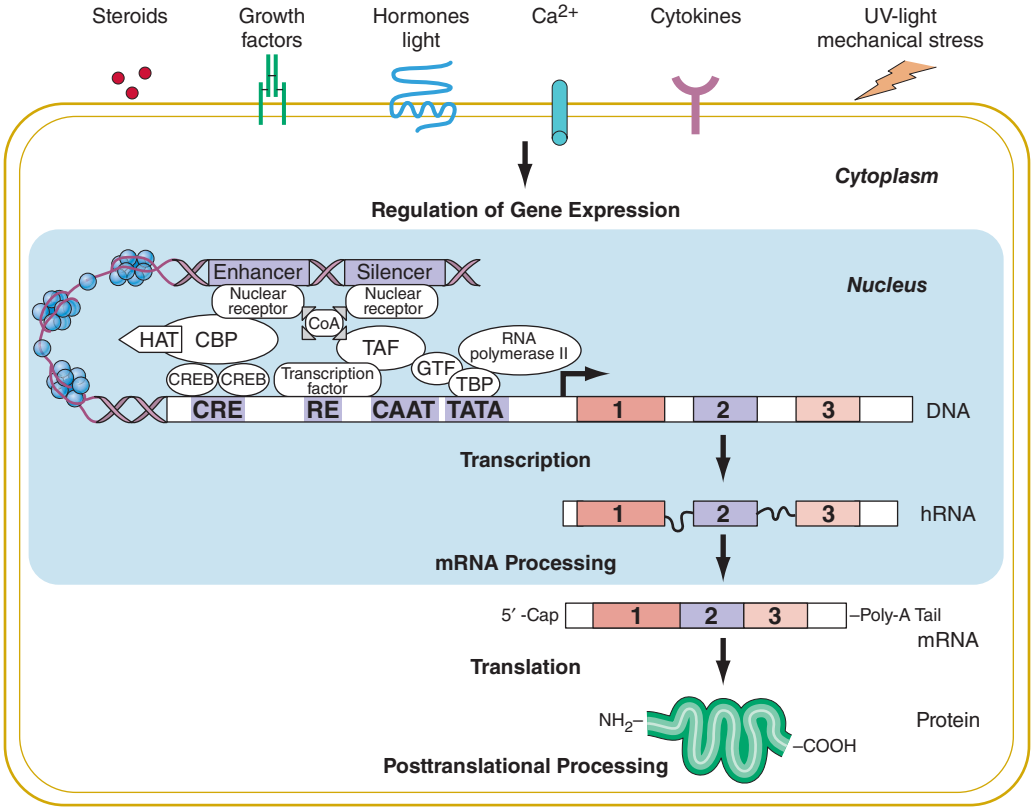

FIGURE 456-2 Flow of genetic information. Multiple extracellular signals activate intracellular signal cascades that result in altered regulation of gene expression through the interaction of transcription factors with regulatory regions of genes. RNA polymerase transcribes DNA into RNA that is processed to mRNA by excision of intronic sequences. The mRNA is translated into a polypeptide chain to form the mature protein after undergoing posttranslational processing. CBP, CREB-binding protein; CoA, co-activator; COOH, carboxyterminus; CRE, cyclic AMP responsive element; CREB, cyclic AMP response element–binding protein; GTF, general transcription factors; HAT, histone acetyl transferase; NH2, aminoterminus; RE, response element; TAF, TBP-associated factors; TATA, TATA box; TBP, TATA-binding protein.

of DNA synthesis requires stringent fidelity in order to avoid transmitting errors to subsequent generations of cells. Genetic abnormalities of DNA mismatch/repair include xeroderma pigmentosum, Bloom's syndrome, ataxia telangiectasia, and hereditary nonpolyposis colon cancer (HNPCC), among others. Many of these disorders strongly predispose to neoplasia because of the rapid acquisition of additional mutations **(Chap. 67)**. After completion of DNA synthesis, cells enter G_2 and progress through a second checkpoint before entering mitosis. At this stage, the chromosomes condense and are aligned along the equatorial plate at metaphase. The two identical sister chromatids, held together at the centromere, divide and migrate to opposite poles of the cell. After formation of a nuclear membrane around the two separated sets of chromatids, the cell divides and two daughter cells are formed, thus restoring the diploid ($2n$) state.

Assortment and Segregation of Genes During Meiosis

Meiosis occurs only in germ cells of the gonads. It shares certain features with mitosis but involves two distinct steps of cell division that reduce the chromosome number to the haploid state. In addition, there is active recombination that generates genetic diversity. During the first cell division, two sister chromatids ($2n \rightarrow 4n$) are formed for each chromosome pair and there is an exchange of DNA between homologous paternal and maternal chromosomes. This process involves the formation of *chiasmata*, structures that correspond to the DNA segments that cross over between the maternal and paternal homologues **(Fig. 456-6)**. Usually there is at least one crossover on each chromosomal arm; recombination occurs more frequently in female meiosis than in male meiosis. Subsequently, the chromosomes segregate randomly. Because there are 23 chromosomes, there exist 2^{23} (>8 million) possible combinations of chromosomes. Together with the genetic exchanges that occur during recombination, chromosomal segregation generates tremendous diversity, and each gamete is genetically unique. The process of recombination and the independent segregation of chromosomes provide the foundation for performing linkage analyses, whereby one attempts to correlate the inheritance of certain chromosomal regions (or linked genes) with the presence of a disease or genetic trait (see below).

After the first meiotic division, which results in two daughter cells ($2n$), the two chromatids of each chromosome separate during a second meiotic division to yield four gametes with a haploid state ($1n$). When the egg is fertilized by sperm, the two haploid sets are combined, thereby restoring the diploid state ($2n$) in the zygote.

REGULATION OF GENE EXPRESSION

Regulation by Transcription Factors The expression of genes is regulated by DNA-binding proteins that activate or repress transcription. The number of DNA sequences and transcription factors that regulate transcription is much greater than originally anticipated. Most genes contain at least 15–20 discrete regulatory elements within 300 bp of the transcription start site. This densely packed promoter region often contains binding sites for ubiquitous transcription factors. However, factors involved in cell-specific expression may also bind to these sequences. Key regulatory elements may also reside at a large distance from the proximal promoter. The globin and the immunoglobulin genes, for example, contain *locus control regions* that are several kilobases away from the structural sequences of the gene. Specific groups of transcription factors that bind to these promoter and enhancer sequences provide a combinatorial code for regulating transcription. In this manner, relatively ubiquitous factors interact with more restricted factors to allow each gene to be expressed and regulated in a unique manner that is dependent on developmental state, cell type, and numerous extracellular stimuli. Regulatory factors also bind within the gene itself, particularly in the intronic regions. The transcription factors that bind to DNA actually represent only the first level of regulatory control. Other proteins—*co-activators* and *co-repressors*—interact with the DNA-binding transcription factors to

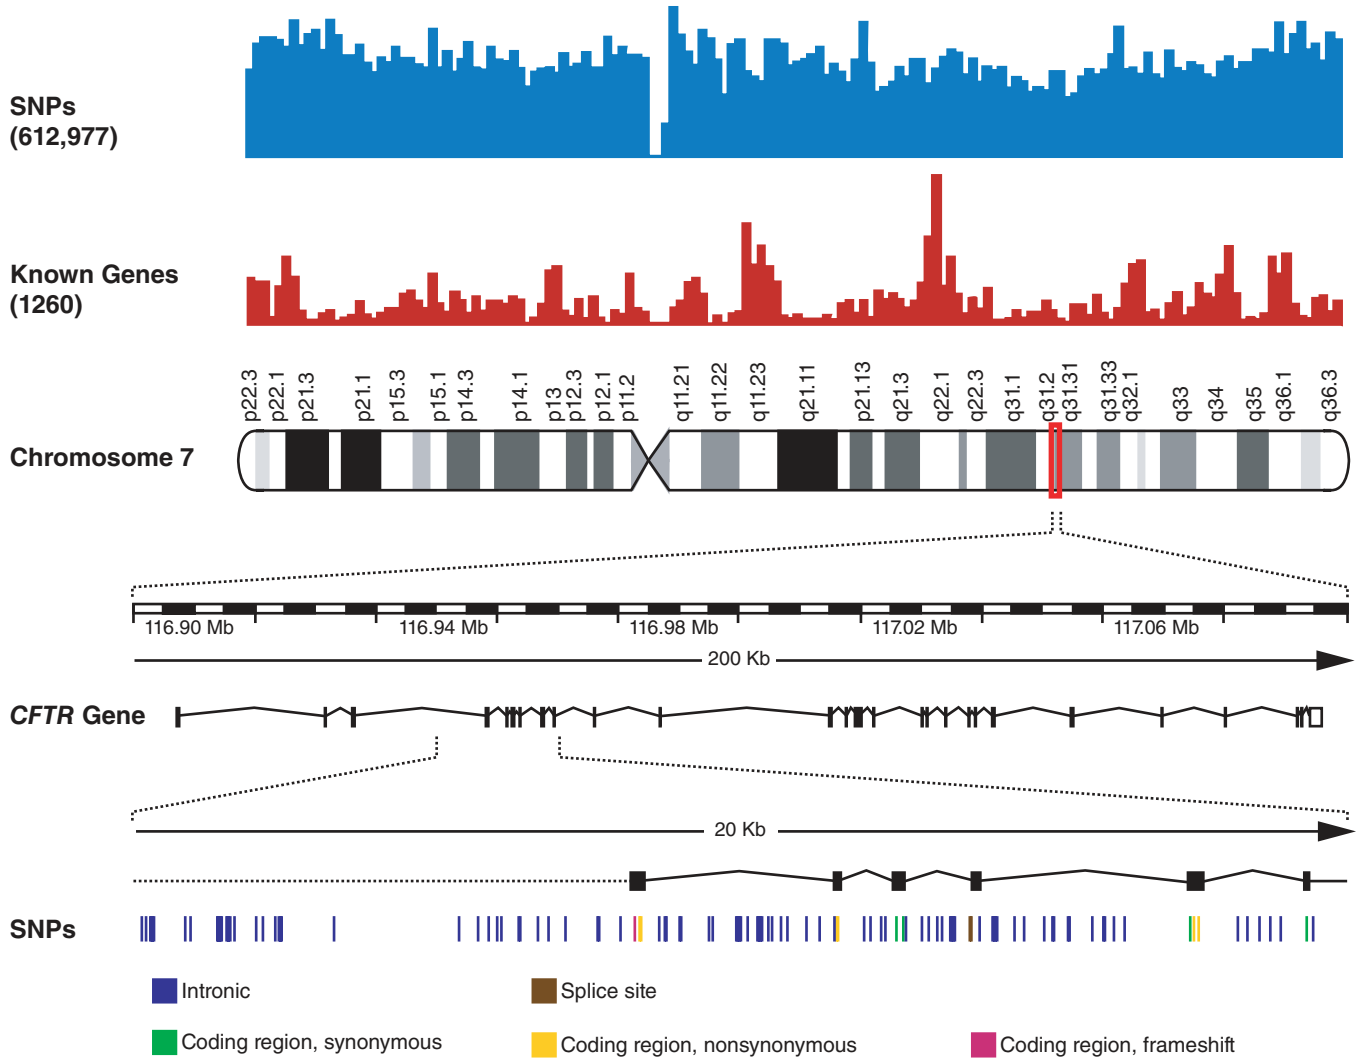

FIGURE 456-3 Chromosome 7 is shown with the density of single-nucleotide polymorphisms (SNPs) and genes above. A 200-kb region in 7q31.2 containing the *CFTR* gene is shown below. The *CFTR* gene contains 27 exons. Close to 2000 mutations in this gene have been found in patients with cystic fibrosis. A 20-kb region encompassing exons 4–9 is shown further amplified to illustrate the SNPs in this region.

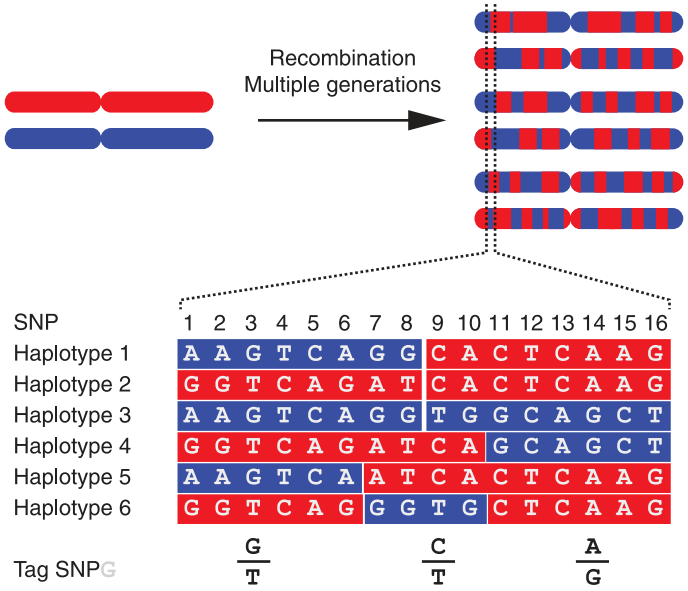

FIGURE 456-4 The origin of haplotypes is due to repeated recombination events occurring in multiple generations. Over time, this leads to distinct haplotypes. These haplotype blocks can often be characterized by genotyping selected Tag single-nucleotide polymorphisms (SNPs), an approach that facilitates performing genome-wide association studies (GWAS).

generate large regulatory complexes. These complexes are subject to control by numerous cell-signaling pathways and enzymes, leading to phosphorylation, acetylation, sumoylation, and ubiquitination. Ultimately, the recruited transcription factors interact with, and stabilize, components of the basal transcription complex that assembles at the site of the TATA box and initiator region. This basal transcription factor complex consists of >30 different proteins. Gene transcription occurs when RNA polymerase begins to synthesize RNA from the DNA template. A large number of identified genetic diseases involve transcription factors (Table 456-2).

The field of *functional genomics* is based on the concept that understanding alterations of gene expression under various physiologic and pathologic conditions provides insight into the underlying functional role of the gene. The ENCODE (ENCyclopedia Of DNA Elements) project aims to compile and annotate all functional sequences in the human genome. By revealing specific gene expression profiles, this knowledge may be of diagnostic and therapeutic relevance. The large-scale study of expression profiles, which takes advantage of micro and bead array technologies, is also referred to as *transcriptomics* because the complement of mRNAs transcribed by the cellular genome is called the *transcriptome*.

Most studies of gene expression have focused on the regulatory DNA elements of genes that control transcription. However, it should be emphasized that gene expression requires a series of steps, including mRNA processing, protein translation, and posttranslational modifications, all of which are actively regulated (Fig. 456-2).

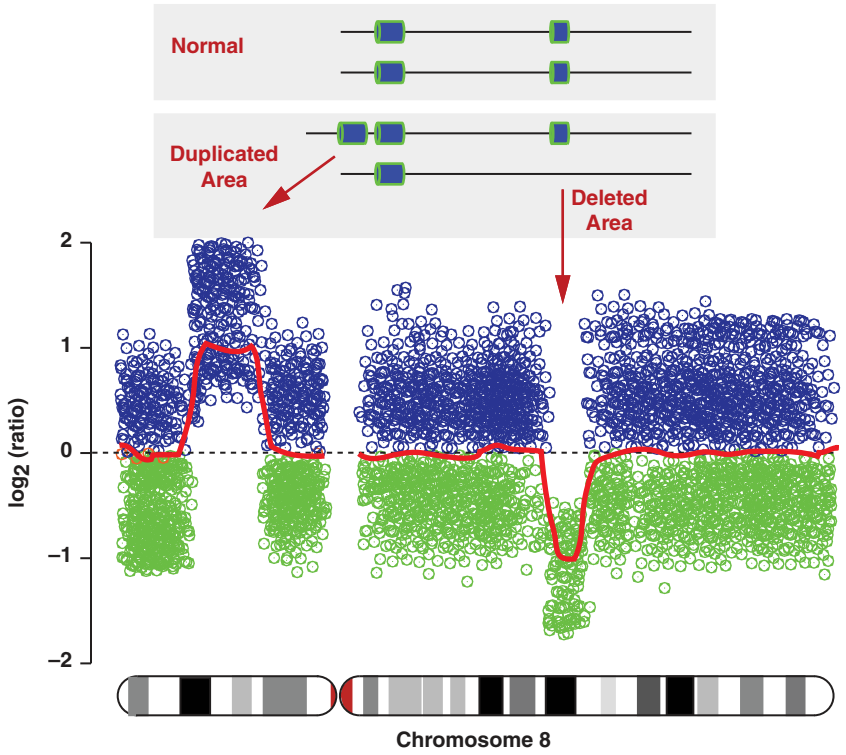

FIGURE 456-5 Copy number variations (CNV) encompass relatively large regions of the genome that have been duplicated or deleted. Chromosome 8 is shown with CNV detected by genomic hybridization. An increase in the signal strength indicates a duplication, a decrease reflects a deletion of the covered chromosomal regions.

Epigenetic Regulation of Gene Expression (see Chap. 471)

Epigenetics describes mechanisms and phenotypic changes that are not a result of variation in the primary DNA nucleotide sequence, but are caused by secondary modifications of DNA or histones. These modifications include heritable changes such as X-inactivation and imprinting, but they can also result from dynamic posttranslational protein modifications in response to environmental influences such as diet, age, or drugs. The epigenetic modifications result in altered expression of individual genes or chromosomal loci encompassing multiple genes. The term *epigenome* describes the constellation of covalent modifications of DNA and histones that impact chromatin structure, as well as noncoding transcripts that modulate the transcriptional activity of DNA. Although the primary DNA sequence is usually identical in all cells of an organism, tissue-specific changes in the epigenome contribute to determining the transcriptional signature of a cell (transcriptome) and hence the protein expression profile (proteome).

Mechanistically, DNA and histone modifications can result in the activation or silencing of gene expression (Fig. 456-7). DNA methylation involves the addition of a methyl group to cytosine residues. This is usually restricted to cytosines of CpG dinucleotides, which are abundant throughout the genome. Methylation of these dinucleotides is thought to represent a defense mechanism that minimizes the expression of sequences that have been incorporated into the genome such as retroviral sequences. CpG dinucleotides also exist in so-called *CpG islands*, stretches of DNA characterized by a high CG content, which are found in the majority of human gene promoters. CpG islands in promoter regions are typically unmethylated, and the lack of methylation facilitates transcription.

Histone methylation involves the addition of a methyl group to lysine residues in histone proteins (Fig. 456-7). Depending on the specific lysine residue being methylated, this alters chromatin configuration, either making it more open or tightly packed. Acetylation of histone proteins is another well-characterized mechanism that results in an open chromatin configuration, which favors active transcription. Acetylation is generally more dynamic than methylation, and many transcriptional activation complexes have histone acetylase activity, whereas repressor complexes often contain deacetylases and remove acetyl groups from histones. Other histone modifications, whose effects are incompletely characterized, include phosphorylation and sumoylation. Lastly, noncoding RNAs that bind to DNA can have a significant impact on transcriptional activity.

Physiologically, epigenetic mechanisms play an important role in several instances. For example, X-inactivation refers to the relative silencing of one of the two X chromosome copies present in females. The inactivation process is a form of dosage compensation such that females (XX) do not generally express twice as many X-chromosomal gene products as males (XY). In a given cell, the choice of which chromosome is inactivated occurs randomly in humans. But once the maternal or paternal X chromosome is inactivated, it will remain inactive, and this information is transmitted with each cell division. The *X-inactive specific transcript* (*Xist*) gene encodes a large noncoding RNA that mediates the silencing of the X chromosome from which it is transcribed by coating it with Xist RNA. The inactive X chromosome is highly methylated and has low levels of histone acetylation. While the majority of X-chromosomal genes are silenced by X-inactivation, about 15% escape inactivation and are expressed.

Epigenetic gene inactivation also occurs on selected chromosomal regions of autosomes, a phenomenon referred to as *genomic imprinting*. Through this mechanism, a small subset of genes is only expressed in a monoallelic fashion. Imprinting is heritable and leads to the preferential expression of one of the parental alleles, which deviates from the usual biallelic expression seen for the majority of genes. Remarkably, imprinting can

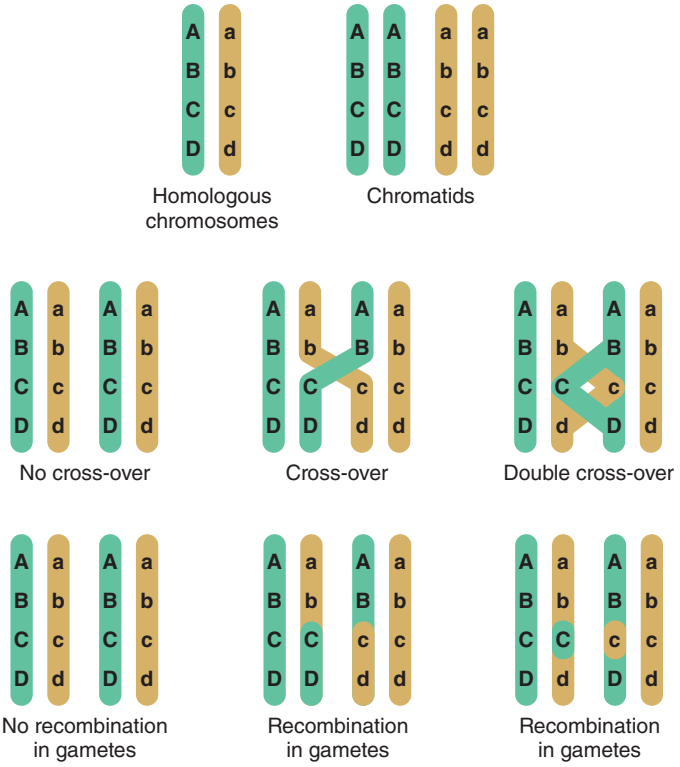

FIGURE 456-6 Crossing-over and genetic recombination. During chiasma formation, either of the two sister chromatids on one chromosome pairs with one of the chromatids of the homologous chromosome. Genetic recombination occurs through crossing-over and results in recombinant and nonrecombinant chromosome segments in the gametes. Together with the random segregation of the maternal and paternal chromosomes, recombination contributes to genetic diversity and forms the basis of the concept of linkage.

TABLE 456-2 Selected Examples of Diseases Caused by Mutations and Rearrangements in Transcription Factors

TRANSCRIPTION FACTOR CLASS	EXAMPLE	ASSOCIATED DISORDER
Nuclear receptors	Androgen receptor	Complete or partial androgen insensitivity (recessive missense mutations) Spinobulbar muscular atrophy (CAG repeat expansion)
Zinc finger proteins	WT1	WAGR syndrome: *W*ilms' tumor, *a*niridia, *g*enitourinary malformations, mental *r*etardation
Basic helix-loop-helix	MITF	Waardenburg's syndrome type 2A
Homeobox	IPF1	Maturity onset of diabetes mellitus type 4 (heterozygous mutation/haploinsufficiency) Pancreatic agenesis (homozygous mutation)
Leucine zipper	Retina leucine zipper (NRL)	Autosomal dominant retinitis pigmentosa
High mobility group (HMG) proteins	SRY	Sex reversal
Forkhead	HNF4α, HNF1α, HNF1β	Maturity onset of diabetes mellitus types 1, 3, 5
Paired box	PAX3	Waardenburg's syndrome types 1 and 3
T-box	TBX5	Holt-Oram syndrome (thumb anomalies, atrial or ventricular septum defects, phocomelia)
Cell cycle control proteins	P53	Li-Fraumeni syndrome, other cancers
Co-activators	CREB binding protein (CBP)	Rubinstein-Taybi syndrome
General transcription factors	TATA-binding protein (TBP)	Spinocerebellar ataxia 17 (CAG expansion)
Transcription elongation factor	VHL	von Hippel–Lindau syndrome (renal cell carcinoma, pheochromocytoma, pancreatic tumors, hemangioblastomas) Autosomal dominant inheritance, somatic inactivation of second allele (Knudson two-hit model)
Runt	CBFA2	Familial thrombocytopenia with propensity to acute myelogenous leukemia
Chimeric proteins due to translocations	PML-RAR	Acute promyelocytic leukemia t(15;17)(q22;q11.2-q12) translocation

Abbreviations: CREB, cAMP responsive element–binding protein; HNF, hepatocyte nuclear factor; PML, promyelocytic leukemia; RAR, retinoic acid receptor; SRY, sex-determining region Y; VHL, von Hippel–Lindau.

be limited to a subset of tissues. Imprinting is mediated through DNA methylation of one of the alleles. The epigenetic marks on imprinted genes are maintained throughout life, but during zygote formation, they are activated or inactivated in a sex-specific manner (imprint reset) **(Fig. 456-8)**, which allows a differential expression pattern in the fertilized egg and the subsequent mitotic divisions. Appropriate expression of imprinted genes is important for normal development and cellular functions. Imprinting defects and uniparental disomy, which is the inheritance of two chromosomes or chromosomal regions from the same parent, are the cause of several developmental disorders such as Beckwith-Wiedemann syndrome, Silver-Russell syndrome, Angelman's syndrome, and Prader-Willi syndrome (see below). Monoallelic loss-of-function mutations in the *GNAS1* gene lead to Albright's hereditary osteodystrophy (AHO). Paternal transmission of *GNAS1* mutations leads to an isolated AHO phenotype (pseudopseudohypoparathyroidism), whereas maternal transmission leads to AHO in combination with hormone resistance to parathyroid hormone, thyrotropin, and gonadotropins (pseudohypoparathyroidism type IA). These phenotypic differences are explained by tissue-specific imprinting of the *GNAS1* gene, which is expressed primarily from the maternal allele in the thyroid, gonadotropes, and the proximal renal tubule. In most other tissues, the *GNAS1* gene is expressed biallelically. In patients with isolated renal resistance to parathyroid hormone (pseudohypoparathyroidism type IB), defective imprinting of the *GNAS1* gene results in decreased Gsα expression in the proximal renal tubules. Rett's syndrome is an X-linked dominant disorder resulting in developmental regression and stereotypic hand movements in affected girls. It is caused by mutations in the *MECP2* gene, which encodes a methyl-binding protein. The ensuing aberrant methylation results in abnormal gene expression in neurons, which are otherwise normally developed.

Remarkably, epigenetic differences also occur among monozygotic twins. Although twins are epigenetically indistinguishable during the early years of life, older monozygotic twins exhibit differences in the overall content and genomic distribution of DNA methylation and histone acetylation, which would be expected to alter gene expression in various tissues.

In cancer, the epigenome is characterized by simultaneous losses and gains of DNA methylation in different genomic regions, as well as repressive histone modifications. Hyper- and hypomethylation are associated with mutations in genes that control DNA methylation. Hypomethylation is thought to remove normal control mechanisms that prevent expression of repressed DNA regions. It is also associated with genomic instability. Hypermethylation, in contrast, results in the silencing of CpG islands in promoter regions of genes, including tumor-suppressor genes. Epigenetic alterations are considered to be more easily reversible compared to genetic changes and modification of the epigenome with demethylating agents and histone deacetylases is being used in the treatment of various malignancies.

TRANSMISSION OF GENETIC DISEASE

Origins and Types of Mutations The term *mutation* is used to designate the process of generating genetic variations as well as the outcome of these alterations. A *mutation* can be defined as any change in the primary nucleotide sequence of DNA regardless of its functional consequences, although it often has a negative connotation. The more neutral term *variation* is now increasingly used to describe sequence changes and is recommended by several professional organizations and guidelines instead of *mutation*. Some variations may be lethal, others are less deleterious, and some may confer an evolutionary advantage. Variations can occur in the germline (sperm or oocytes); these can be transmitted to progeny. Alternatively, variations can occur during embryogenesis or in somatic tissues. Variations that occur during development lead to *mosaicism*, a situation in which tissues are composed of cells with different genetic constitutions. If the germline is mosaic, a mutation can be transmitted to some progeny but not others, which sometimes leads to confusion in assessing the pattern of inheritance. Somatic mutations that do not affect cell survival can sometimes be detected because of variable phenotypic effects in tissues (e.g., pigmented lesions in McCune-Albright syndrome). Other somatic mutations are associated with neoplasia because they confer a growth advantage to cells. Epigenetic events may also influence gene expression or facilitate genetic damage. With the exception of triplet nucleotide repeats, which can expand (see below), variations are usually stable.

Mutations are structurally diverse—they can involve the entire genome, as in triploidy (one extra set of chromosomes), or gross numerical or structural alterations in chromosomes or individual genes. Large deletions may affect a portion of a gene or an entire gene, or, if several genes are involved, they may lead to a *contiguous gene syndrome*. Unequal crossing-over between homologous genes can result in fusion gene mutations, as illustrated by color blindness. Variations involving single nucleotides are referred to as *point mutations*. Substitutions are called *transitions* if a purine is replaced by another purine base (A ↔ G) or if a pyrimidine is replaced by another pyrimidine (C ↔ T).

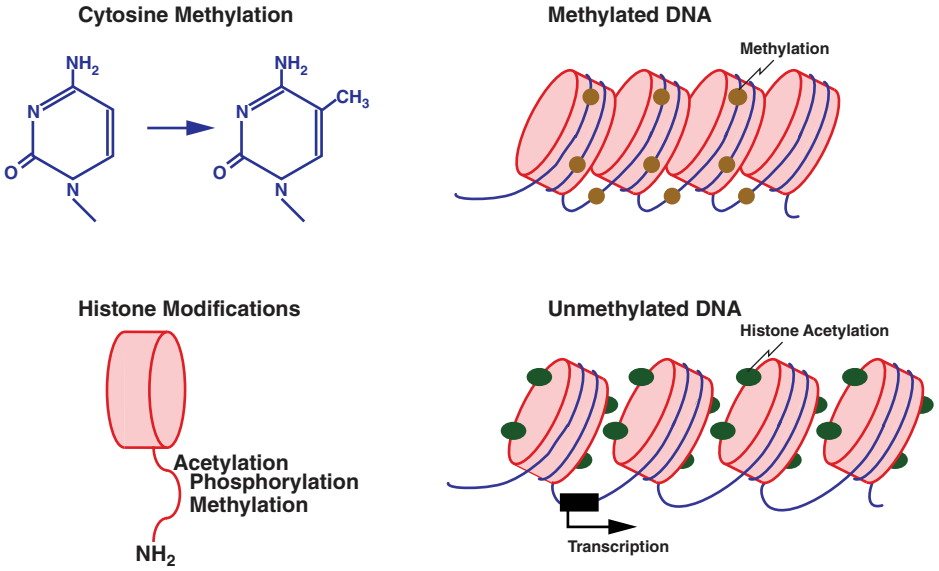

FIGURE 456-7 Epigenetic modifications of DNA and histones. Methylation of cytosine residues is associated with gene silencing. Methylation of certain genomic regions is inherited (imprinting), and it is involved in the silencing of one of the two X chromosomes in females (X-inactivation). Alterations in methylation can also be acquired, e.g., in cancer cells. Covalent posttranslational modifications of histones play an important role in altering DNA accessibility and chromatin structure and hence in regulating transcription. Histones can be reversibly modified in their amino-terminal tails, which protrude from the nucleosome core particle, by acetylation of lysine, phosphorylation of serine, methylation of lysine and arginine residues, and sumoylation. Acetylation of histones by histone acetylases (HATs), e.g., leads to unwinding of chromatin and accessibility to transcription factors. Conversely, deacetylation by histone deacetylases (HDACs) results in a compact chromatin structure and silencing of transcription.

Changes from a purine to a pyrimidine, or vice versa, are referred to as *transversions*. If the DNA sequence change occurs in a coding region and alters an amino acid, it is called a *missense mutation*. Depending on the functional consequences of such a missense mutation, amino acid substitutions in different regions of the protein can lead to distinct phenotypes.

Variations can occur in all domains of a gene **(Fig. 456-9)**. A point mutation occurring within the coding region leads to an amino acid substitution if the codon is altered **(Fig. 456-10)**. Point mutations that introduce a premature stop codon result in a truncated or missing protein. Large deletions may affect a portion of a gene or an entire gene, whereas small deletions and insertions alter the reading frame if they do not represent a multiple of three bases. These "frameshift" mutations, now also designated as *amphigoric* amino acid changes, lead to an entirely altered carboxy terminus. Mutations in intronic sequences or in exon junctions may destroy or create splice donor or splice acceptor sites. Variations may also be found in the regulatory sequences of genes, resulting in reduced or enhanced gene transcription.

Certain DNA sequences are particularly susceptible to mutagenesis. Successive pyrimidine residues (e.g., T-T or C-C) are subject to the formation of ultraviolet light–induced photoadducts. If these pyrimidine dimers are not repaired by the nucleotide excision repair pathway, mutations will be introduced after DNA synthesis. The dinucleotide C-G, or CpG, is also a hot spot for a specific type of mutation. In this case, methylation of the cytosine is associated with an enhanced rate of deamination to uracil, which is then replaced with thymine. This C → T transition (or G → A on the opposite strand) accounts for at least one-third of point mutations associated with polymorphisms and mutations. In addition to the fact that certain types of mutations (C → T or G → A) are relatively common, the nature of the genetic code also results in overrepresentation of certain amino acid substitutions.

Polymorphisms are sequence variations that have a frequency of at least 1%. Usually, they do not result in a perceptible phenotype but because allele frequency and functional consequences are often not known, the term variation is now increasingly recommended for the description of these sequence changes. Often they consist of single base-pair substitutions that do not alter the protein coding sequence because of the degenerate nature of the genetic code (synonymous polymorphism), although it is possible that some might alter mRNA stability, translation, or the amino acid sequence (nonsynonymous polymorphism) (Fig. 456-10). The detection of sequence variants poses a practical problem because it is often unclear whether it creates a change with functional consequences or a benign variation. In this situation, the sequence alteration is also described as *variant of unknown significance (VUS)*.

MUTATION RATES Mutations represent an important cause of genetic diversity as well as disease. Mutation rates are difficult to determine in humans because many mutations are silent and because testing is often not adequate to detect the phenotypic consequences. Mutation rates vary in different genes but are estimated to occur at a rate of ~10^{-10}/bp per cell division. Germline mutation rates (as opposed to somatic mutations) are relevant in the transmission of genetic disease. Because the population of oocytes is established very early in development, only ~20 cell divisions are required for completed oogenesis, whereas spermatogenesis involves ~30 divisions by the time of puberty and 20 cell divisions each year thereafter. Consequently, the probability of acquiring new point mutations is much greater in the male germline than the female germline, in which rates of aneuploidy are increased. Thus, the incidence of new point mutations in spermatogonia increases with paternal age (e.g., achondrodysplasia, Marfan's syndrome, neurofibromatosis). It is estimated that about 1 in 10 sperm carries a new deleterious mutation. The rates for new mutations are calculated most readily for autosomal dominant and X-linked disorders and are ~10^{-5}–10^{-6}/locus per generation. Because most monogenic diseases are relatively rare, new mutations account for a significant fraction of cases. This is important in the context of genetic counseling, because a new mutation can be transmitted to the affected individual but does not necessarily imply that the parents are at risk to transmit the disease to other children. An exception to this is when the new mutation occurs early in germline development, leading to *gonadal mosaicism*.

UNEQUAL CROSSING-OVER Normally, DNA recombination in germ cells occurs with remarkable fidelity to maintain the precise junction sites for the exchanged DNA sequences (Fig. 456-6). However, mispairing of homologous sequences leads to unequal crossover, with gene duplication on one of the chromosomes and gene deletion on the other chromosome. A significant fraction of growth hormone (*GH*) gene deletions, for example, involve unequal crossing-over **(Chap. 372)**. The *GH* gene is a member of a large gene cluster that includes a GH variant gene as well as several structurally related chorionic somatomammotropin genes and pseudogenes (highly homologous but functionally inactive relatives of a normal gene). Because such gene clusters contain multiple homologous DNA sequences arranged in tandem, they are particularly prone to undergo recombination and, consequently, gene duplication or deletion. On the other hand, duplication of the *PMP22* gene because of unequal crossing-over results in increased gene dosage and type IA Charcot-Marie-Tooth disease. Unequal crossing-over resulting in deletion of *PMP22* causes a distinct neuropathy called *hereditary liability to pressure palsy* **(Chap. 438)**.

Glucocorticoid-remediable aldosteronism (GRA) is caused by a gene fusion or rearrangement involving the genes that encode aldosterone synthase (*CYP11B2*) and steroid 11β-hydroxylase (*CYP11B1*), normally arranged in tandem on chromosome 8q. These two genes are 95%

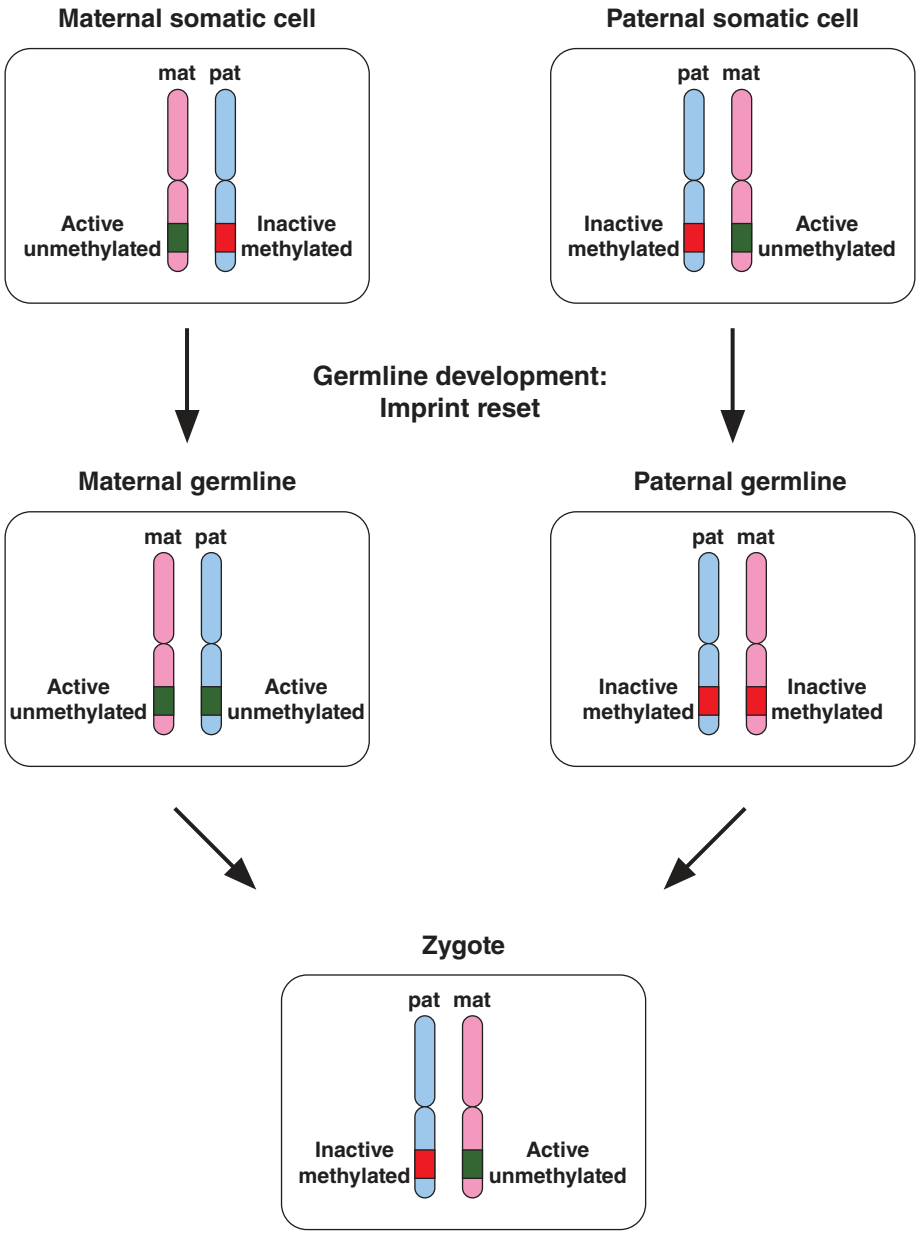

FIGURE 456-8 A few genomic regions are imprinted in a parent-specific fashion. The unmethylated chromosomal regions are actively expressed, whereas the methylated regions are silenced. In the germline, the imprint is reset in a parent-specific fashion: both chromosomes are unmethylated in the maternal (mat) germline and methylated in the paternal (pat) germline. In the zygote, the resulting imprinting pattern is identical with the pattern in the somatic cells of the parents.

identical, predisposing to gene duplication and deletion by unequal crossing-over. The rearranged gene product contains the regulatory regions of 11β-hydroxylase fused to the coding sequence of aldosterone synthetase. Consequently, the latter enzyme is expressed in the adrenocorticotropic hormone (ACTH)–dependent zona fasciculata of the adrenal gland, resulting in overproduction of mineralocorticoids and hypertension **(Chap. 379)**.

Gene conversion refers to a nonreciprocal exchange of homologous genetic information. It has been used to explain how an internal portion of a gene is replaced by a homologous segment copied from another allele or locus; these genetic alterations may range from a few nucleotides to a few thousand nucleotides. As a result of gene conversion, it is possible for short DNA segments of two chromosomes to be identical, even though these sequences are distinct in the parents. A practical consequence of this phenomenon is that nucleotide substitutions can occur during gene conversion between related genes, often altering the function of the gene. In disease states, gene conversion often involves intergenic exchange of DNA between a gene and a related pseudogene. For example, the 21-hydroxylase gene (*CYP21A2*) is adjacent to a nonfunctional pseudogene (*CYP21A1P*). Many of the nucleotide substitutions that are found in the *CYP21A2* gene in patients with congenital adrenal hyperplasia correspond to sequences that are present in the *CYP21A1P* pseudogene, suggesting gene conversion as one cause of mutagenesis. In addition, mitotic gene conversion has been suggested as a mechanism to explain revertant mosaicism in which an inherited mutation is "corrected" in certain cells. For example, patients with autosomal recessive generalized atrophic benign epidermolysis bullosa have acquired reverse mutations in one of the two mutated *COL17A1* alleles, leading to clinically unaffected patches of skin.

INSERTIONS AND DELETIONS Although many instances of insertions and deletions occur as a consequence of unequal crossing-over, there is also evidence for internal duplication, inversion, or deletion of DNA sequences. The fact that certain deletions or insertions appear to occur repeatedly as independent events indicates that specific regions within the DNA sequence predispose to these errors. For example, certain regions of the *DMD* gene, which encodes dystrophin, appear to be hot spots for deletions and result in muscular dystrophy **(Chap. 441)**. Some regions within the human genome are rearrangement hot spots and lead to CNVs.

ERRORS IN DNA REPAIR Because mutations caused by defects in DNA repair accumulate as somatic cells divide, these types of mutations are particularly important in the context of neoplastic disorders. Several genetic disorders involving DNA repair enzymes underscore their importance. Patients with xeroderma pigmentosum have defects in DNA damage recognition or in the nucleotide excision and repair pathway **(Chap. 72)**. Exposed skin is dry and pigmented and is extraordinarily sensitive to the mutagenic effects of ultraviolet irradiation. More than 10 different genes have been shown to cause the different forms of xeroderma pigmentosum. This finding is consistent with the earlier classification of this disease into different complementation groups in which normal function is rescued by the fusion of cells derived from two different forms of xeroderma pigmentosum.

Ataxia telangiectasia causes large telangiectatic lesions of the face, cerebellar ataxia, immunologic defects, and hypersensitivity to ionizing radiation **(Chap. 431)**. The discovery of the ataxia telangiectasia mutated (*ATM*) gene reveals that it is homologous to genes involved in DNA repair and control of cell cycle checkpoints. Mutations in the *ATM* gene give rise to defects in meiosis as well as increasing susceptibility to damage from ionizing radiation. Fanconi's anemia is also associated with an increased risk of multiple acquired genetic abnormalities. It is characterized by diverse congenital anomalies and a strong predisposition to develop aplastic anemia and acute myelogenous leukemia **(Chap. 100)**. Cells from these patients are susceptible to chromosomal breaks caused by a defect in genetic recombination. Currently, at least 16 different complementation groups have been identified, and the genes associated with Fanconi's anemia have been cloned. HNPCC (Lynch's syndrome) is characterized by autosomal dominant transmission of colon cancer, young age (<50 years) of presentation, predisposition

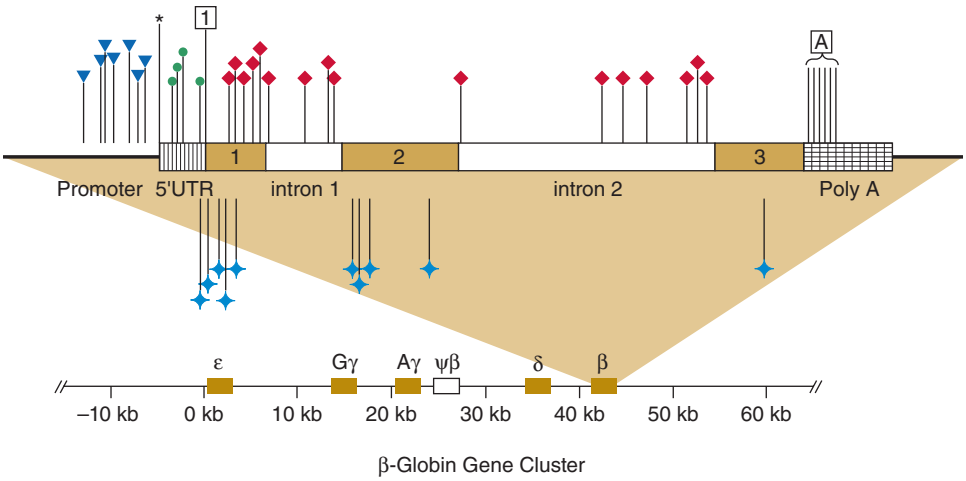

FIGURE 456-9 Point mutations causing β thalassemia as example of allelic heterogeneity. The β-globin gene is located in the globin gene cluster. Point mutations can be located in the promoter, the CAP site, the 5'-untranslated region, the initiation codon, each of the three exons, the introns, or the polyadenylation signal. Many mutations introduce missense or nonsense mutations, whereas others cause defective RNA splicing. Not shown here are deletion mutations of the β-globin gene or larger deletions of the globin locus that can also result in thalassemia. ▼, promoter mutations; *, CAP site; ●, 5'UTR; 1, initiation codon; ◆, defective RNA processing; ✦, missense and nonsense mutations; A, Poly A signal.

to lesions in the proximal large bowel, and associated malignancies such as uterine cancer and ovarian cancer. HNPCC is predominantly caused by mutations in one of several different mismatch repair (MMR) genes including MutS homologue 2 (*MSH2*), MutL homologue 1 and 6 (*MLH1, MLH6*), *MSH6*, *PMS1*, and *PMS2* **(Chap. 77)**. These proteins are involved in the detection of nucleotide mismatches and in the recognition of slipped-strand trinucleotide repeats. Germline mutations in these genes lead to microsatellite instability and a high mutation rate in colon cancer. Genetic screening tests for this disorder are now being used for families considered to be at risk. Recognition of HNPCC allows early screening with colonoscopy and the implementation of prevention strategies using nonsteroidal anti-inflammatory drugs.

UNSTABLE DNA SEQUENCES *Trinucleotide repeats* may be unstable and expand beyond a critical number. Mechanistically, the expansion is thought to be caused by unequal recombination and slipped mispairing. A premutation represents a small increase in trinucleotide copy number. In subsequent generations, the expanded repeat may increase further in length and result in an increasingly severe phenotype, a process called *dynamic mutation* (see below for discussion of anticipation). Trinucleotide expansion was first recognized as a cause of the fragile X syndrome, one of the most common causes of intellectual disability. Other disorders arising from a similar mechanism include Huntington's disease, X-linked spinobulbar muscular atrophy, and myotonic dystrophy. Malignant cells are also characterized by genetic instability, indicating a breakdown in mechanisms that regulate DNA repair and the cell cycle.

Functional Consequences of Mutations Functionally, mutations can be broadly classified as gain-of-function and loss-of-function mutations. Gain-of-function mutations are typically dominant (e.g., they result in phenotypic alterations when a single allele is affected). Inactivating mutations are usually recessive, and an affected individual is homozygous or compound heterozygous (e.g., carrying two different mutant alleles of the same gene) for the disease-causing mutations. Alternatively, mutation in a single allele can result in *haploinsufficiency*, a situation in which one normal allele is not sufficient to maintain a normal phenotype. Haploinsufficiency is a commonly observed mechanism in diseases associated with mutations in transcription factors (Table 456-2). Remarkably, the clinical features among patients with an identical mutation often vary significantly. One mechanism underlying this variability consists in the influence of modifying genes. Haploinsufficiency can also affect the expression of rate-limiting enzymes. For example, haploinsufficiency in enzymes involved in heme synthesis can cause porphyrias **(Chap. 409)**.

An increase in dosage of a gene product may also result in disease, as illustrated by the duplication of the *DAX1* gene in dosage-sensitive

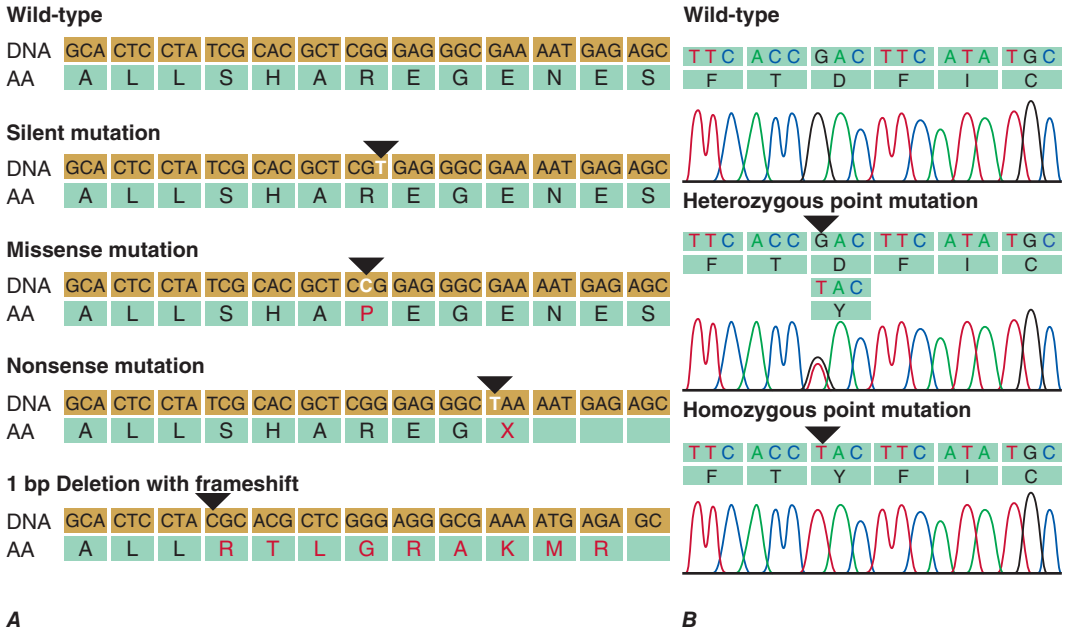

FIGURE 456-10 ***A.*** Examples of mutations (now commonly referred to as *variations*). The coding strand is shown with the encoded amino acid sequence. ***B.*** Chromatograms of sequence analyses after amplification of genomic DNA by polymerase chain reaction.

sex reversal **(Chap. 383)**. Mutation in a single allele can also result in loss of function due to a dominant-negative effect. In this case, the mutated allele interferes with the function of the normal gene product by one of several different mechanisms: (1) a mutant protein may interfere with the function of a multimeric protein complex, as illustrated by mutations in type 1 collagen (*COL1A1*, *COL1A2*) genes in osteogenesis imperfecta **(Chap. 406)**; (2) a mutant protein may occupy binding sites on proteins or promoter response elements, as illustrated by thyroid hormone resistance β, a disorder in which inactivated thyroid hormone receptor β binds to target genes and functions as an antagonist of normal receptors **(Chap. 375)**; or (3) a mutant protein can be cytotoxic as in α_1 antitrypsin deficiency **(Chap. 286)** or autosomal dominant neurohypophyseal diabetes insipidus **(Chap. 374)**, in which the abnormally folded proteins are trapped within the endoplasmic reticulum and ultimately cause cellular damage.

Genotype and Phenotype

• ALLELES, GENOTYPES, AND HAPLOTYPES An observed trait is referred to as a *phenotype*; the genetic information defining the phenotype is called the *genotype*. Alternative forms of a gene or a genetic marker are referred to as *alleles*. Alleles may be polymorphic variants of nucleic acids that have no apparent effect on gene expression or function. In other instances, these variants may have subtle effects on gene expression, thereby conferring adaptive advantages associated with genetic diversity. On the other hand, allelic variants may reflect mutations that clearly alter the function of a gene product. The common Glu6Val (E6V) sickle cell mutation in the β-*globin* gene and the ΔF508 deletion of phenylalanine (F) in the *CFTR* gene are examples of allelic variants of these genes that result in disease. Because each individual has two copies of each chromosome (one inherited from the mother and one inherited from the father), an individual can have only two alleles at a given locus. However, there can be many different alleles in the population. The normal or common allele is usually referred to as *wild type*. When alleles at a given locus are identical, the individual is *homozygous*. Inheriting identical copies of a mutant allele occurs in many autosomal recessive disorders, particularly in circumstances of consanguinity or isolated populations. If the alleles are different on the maternal and the paternal copy of the gene, the individual is *heterozygous* at this locus (Fig. 456-10). If two different mutant alleles are inherited at a given locus, the individual is said to be a *compound heterozygote*. *Hemizygous* is used to describe males with a mutation in an X chromosomal gene or a female with a loss of one X chromosomal locus.

Genotypes describe the specific alleles at a particular locus. For example, there are three common alleles (E2, E3, E4) of the apolipoprotein E (*APOE*) gene. The genotype of an individual can therefore be described as *APOE3/4* or *APOE4/4* or any other variant. These designations indicate which alleles are present on the two chromosomes in the *APOE* gene at locus 19q13.2. In other cases, the genotype might be assigned arbitrary numbers (e.g., 1/2) or letters (e.g., B/b) to distinguish different alleles.

A *haplotype* refers to a group of alleles that are closely linked together at a genomic locus (Fig. 456-4). Haplotypes are useful for tracking the transmission of genomic segments within families and for detecting evidence of genetic recombination, if the crossover event occurs between the alleles (Fig. 456-6). As an example, various alleles at the histocompatibility locus antigen (HLA) on chromosome 6p are used to establish haplotypes associated with certain disease states. For example, 21-hydroxylase deficiency, complement deficiency, and hemochromatosis are each associated with specific HLA haplotypes. It is now recognized that these genes lie in close proximity to the HLA locus, which explains why HLA associations were identified even before the disease genes were cloned and localized. In other cases, specific HLA associations with diseases such as ankylosing spondylitis (HLA-B27) or type 1 diabetes mellitus (HLA-DR4) reflect the role of specific HLA allelic variants in susceptibility to these autoimmune diseases. The characterization of common SNP haplotypes in numerous populations from different parts of the world has provided the necessary tools for association studies designed to detect genes involved in the pathogenesis of complex disorders (Table 456-1). The presence or absence of certain haplotypes can also be relevant for the customized choice of medical therapies (pharmacogenomics) or may have value for preventive strategies.

Genotype-phenotype correlation describes the association of a specific mutation and the resulting phenotype. The phenotype may differ depending on the location or type of the mutation in some genes. For example, in von Hippel–Lindau disease, an autosomal dominant multisystem disease that can include renal cell carcinoma, hemangioblastomas, and pheochromocytomas, among others, the phenotype varies greatly and the identification of the specific mutation can be clinically useful in order to predict the phenotypic spectrum.

ALLELIC HETEROGENEITY *Allelic heterogeneity* refers to the fact that different mutations in the same genetic locus can cause an identical or similar phenotype. For example, many different mutations of the β-globin locus can cause β thalassemia **(Table 456-3)** (Fig. 456-9). In essence, allelic heterogeneity reflects the fact that many different mutations are capable of altering protein structure and function. For this reason, maps of inactivating mutations in genes usually show a near-random distribution. Exceptions include (1) a founder effect, in which a particular mutation that does not affect reproductive capacity can be traced to a single individual; (2) "hot spots" for mutations, in which the nature of the DNA sequence predisposes to a recurring mutation; and (3) localization of mutations to certain domains that are particularly critical for protein function. Allelic heterogeneity creates a practical problem for genetic testing because one must often examine the entire genetic locus for mutations, because these can differ in each patient. For example, about 2000 variants have been identified in the *CFTR* gene to date, although some of them are very rare and some may not be disease-causing (Fig. 456-3). Mutational analysis may initially focus on a panel of mutations that are particularly frequent (often taking the ethnic background of the patient into account), but a negative result does not exclude the presence of a mutation elsewhere in the gene. One should also be aware that mutational analyses tend to focus on the coding region of a gene without considering regulatory and intronic regions. Because disease-causing mutations may be located outside the coding regions, negative results need to be interpreted with caution. The advent of more comprehensive sequencing technologies now greatly facilitates concomitant mutational analyses of several genes after targeted enrichment, or even mutational analysis of the whole exome or genome. However, comprehensive sequencing can result in significant diagnostic challenges because the detection of a sequence alteration alone is not always sufficient to establish that it has a causal role (variants of unknown significance, VUS).

PHENOTYPIC HETEROGENEITY *Phenotypic heterogeneity* occurs when more than one phenotype is caused by allelic mutations (e.g., different mutations in the same gene) (Table 456-3). For example, laminopathies are monogenic multisystem disorders that result from mutations in the *LMNA* gene, which encodes the nuclear lamins A and C. Twelve autosomal dominant and five autosomal recessive disorders are caused by mutations in the *LMNA* gene. They include several forms of lipodystrophies, Emery-Dreifuss muscular dystrophy, progeria syndromes, a form of neuronal Charcot-Marie-Tooth disease (type 2B1), and a group of overlapping syndromes. Remarkably, hierarchical cluster analysis has revealed that the phenotypes vary depending on the position of the mutation (*genotype-phenotype correlation*). Similarly, identical mutations in the *FGFR2* gene can result in very distinct phenotypes: Crouzon's syndrome (craniofacial synostosis) or Pfeiffer's syndrome (acrocephalopolysyndactyly).

LOCUS OR NONALLELIC HETEROGENEITY AND PHENOCOPIES *Nonallelic or locus heterogeneity* refers to the situation in which a similar disease phenotype results from mutations at different genetic loci (Table 456-3). This often occurs when more than one gene product produces different subunits of an interacting complex or when different genes are involved in the same genetic cascade or physiologic pathway. For example, osteogenesis imperfecta can arise from mutations in two different procollagen genes (*COL1A1* or *COL1A2*) that are located on different chromosomes, and can involve multiple other genes **(Chap. 406)**. The effects of inactivating mutations in these two genes are similar because

TABLE 456-3 Selected Examples of Phenotypic Heterogeneity and Locus Heterogeneity

Phenotypic Heterogeneity

GENE, PROTEIN	PHENOTYPE	INHERITANCE	OMIM
LMNA, Lamin A/C	Emery-Dreifuss muscular dystrophy (AD)	AD	181350
	Familial partial lipodystrophy Dunnigan	AD	151660

Locus Heterogeneity

PHENOTYPE	GENE	CHROMOSOMAL LOCATION	PROTEIN
Familial hypertrophic cardiomyopathy	*MYH7*	14q12	Myosin heavy chain beta
Genes encoding sarcomeric proteins	*TNNT2*	1q2	Troponin-T2
	TPM1	15q22.1	Tropomyosin alpha
	MYBPC3	11p11q	Myosin-binding protein C
	TNNI3	19q13.4	Troponin 1
	MYL2	12q23-24.3	Myosin light chain 2
	MYL3	3p	Myosin light chain 3
	TTN	2q24.3	Cardiac titin
	ACTC	15q11	Cardiac alpha actin
	MYH6	14q1	Myosin heavy chain alpha
	MYLK2	20q13.3	Myosin light-peptide kinase
	CAV3	3p25	Caveolin 3
Genes encoding nonsarcomeric proteins	*MTT1*	Mitochondrial	tRNA isoleucine
	MTTG	Mitochondrial	tRNA glycine
	PRKAG2	7q35-q36	AMP-activated protein kinase γ2 subunit
	DMPK	19q13.2-13.3	Myotonin protein kinase (myotonic dystrophy)
	FRDA	9q13	Frataxin (Friedreich's ataxia)
Polycystic kidney disease	*PKD1*	16p13.3-13.12	Polycystin 1 (AD)
	PKD2	4q21.-23	Polycystin 2 (AD)
	PKHD1	6p21.1-p12	Fibrocystin (AR)
Noonan's syndrome	*PTPN11*	12q24.1	Protein-tyrosine phosphatase 2c
	KRAS	12p12.1	KRAS

the protein products comprise different subunits of the helical collagen fiber. Similarly, muscular dystrophy syndromes can be caused by mutations in various genes, consistent with the fact that it can be transmitted in an X-linked (Duchenne or Becker), autosomal dominant (limb-girdle muscular dystrophy type 1), or autosomal recessive (limb-girdle muscular dystrophy type 2) manner **(Chap. 441)**. Mutations in the X-linked *DMD* gene, which encodes dystrophin, are the most common cause of muscular dystrophy. This feature reflects the large size of the gene as well as the fact that the phenotype is expressed in hemizygous males because they have only a single copy of the X chromosome. Dystrophin is associated with a large protein complex linked to the membrane-associated cytoskeleton in muscle. Mutations in several different components of this protein complex can also cause muscular dystrophy syndromes. Although the phenotypic features of some of these disorders are distinct, the phenotypic spectrum caused by mutations in different genes overlaps, thereby leading to nonallelic heterogeneity. It should be noted that mutations in dystrophin are also associated with allelic heterogeneity. For example, mutations in the *DMD* gene can cause either Duchenne's or the less severe Becker's muscular dystrophy, depending on the severity of the protein defect.

Recognition of nonallelic heterogeneity is important for several reasons: (1) the ability to identify disease loci in linkage studies is reduced by including patients with similar phenotypes but different genetic disorders; (2) genetic testing is more complex because several different genes need to be considered along with the possibility of different mutations in each of the candidate genes; and (3) novel information is gained about how genes or proteins interact, providing unique insights into molecular physiology.

Phenocopies refer to circumstances in which nongenetic conditions mimic a genetic disorder. For example, features of toxin- or drug-induced neurologic syndromes can resemble those seen in Huntington's disease, and vascular causes of dementia share phenotypic features with familial forms of Alzheimer's dementia **(Chap. 423)**. As in nonallelic heterogeneity, the presence of phenocopies has the potential to confound linkage studies and genetic testing. Patient history and subtle differences in phenotype can often provide clues that distinguish these disorders from related genetic conditions.

VARIABLE EXPRESSIVITY AND INCOMPLETE PENETRANCE The same genetic mutation may be associated with a phenotypic spectrum in

different affected individuals, thereby illustrating the phenomenon of *variable expressivity*. This may include different manifestations of a disorder variably involving different organs (e.g., multiple endocrine neoplasia [MEN]), the severity of the disorder (e.g., cystic fibrosis), or the age of disease onset (e.g., Alzheimer's dementia). MEN 1 illustrates several of these features. In this autosomal dominant tumor syndrome, affected individuals carry an inactivating germline mutation that is inherited in an autosomal dominant fashion. After somatic inactivation of the alternate allele (loss of heterozygosity; Knudson two-hit model), they can develop tumors of the parathyroid gland, endocrine pancreas, and the pituitary gland **(Chap. 381)**. However, the pattern of tumors in the different glands, the age at which tumors develop, and the types of hormones produced vary among affected individuals, even within a given family. In this example, the phenotypic variability arises, in part, because of the requirement for a second somatic mutation in the normal copy of the *MEN1* gene, as well as the large array of different cell types that are susceptible to the effects of *MEN1* gene mutations. In part, variable expression reflects the influence of modifier genes, or genetic background, on the effects of a particular mutation. Even in identical twins, in whom the genetic constitution is essentially the same, one can occasionally see variable expression of a genetic disease.

Interactions with the environment can also influence the course of a disease. For example, the manifestations and severity of hemochromatosis can be influenced by iron intake **(Chap. 407)**, and the course of phenylketonuria is affected by exposure to phenylalanine in the diet **(Chap. 413)**. Other metabolic disorders, such as hyperlipidemias and porphyria, also fall into this category. Many mechanisms, including genetic effects and environmental influences, can therefore lead to variable expressivity. In genetic counseling, it is particularly important to recognize this variability, because one cannot always predict the course of disease, even when the mutation is known.

Penetrance refers to the proportion of individuals with a mutant genotype that express the phenotype. If all carriers of a mutant express the phenotype, penetrance is complete, whereas it is said to be *incomplete* or *reduced* if some individuals do not exhibit features of the phenotype. Dominant conditions with incomplete penetrance are characterized by skipping of generations with unaffected carriers transmitting the mutant gene. For example, hypertrophic obstructive cardiomyopathy (HCM) caused by mutations in the *myosin-binding protein C* gene is a dominant disorder with clinical features in only a subset of patients who carry the mutation **(Chap. 254)**. Patients who have the mutation but no evidence of the disease can still transmit the disorder to subsequent generations. In many conditions with postnatal onset, the proportion of gene carriers who are affected varies with age. Thus, when describing penetrance, one has to specify age. For example, for disorders such as Huntington's disease or familial amyotrophic lateral sclerosis, which present later in life, the rate of penetrance is influenced by the age at which the clinical assessment is performed. *Imprinting* can also modify the penetrance of a disease. For example, in patients with AHO, mutations in the Gsα subunit (*GNAS1* gene) are expressed clinically only in individuals who inherit the mutation from their mother **(Chap. 403)**.

SEX-INFLUENCED PHENOTYPES Certain mutations affect males and females quite differently. In some instances, this is because the gene resides on the X or Y sex chromosomes (X-linked disorders and Y-linked disorders). As a result, the phenotype of mutated X-linked genes will be expressed fully in males but variably in heterozygous females, depending on the degree of X-inactivation and the function of the gene. For example, most heterozygous female carriers of factor VIII deficiency (hemophilia A) are asymptomatic because sufficient factor VIII is produced to prevent a defect in coagulation **(Chap. 112)**. On the other hand, some females heterozygous for the X-linked lipid storage defect caused by α-galactosidase A deficiency (Fabry's disease) experience mild manifestations of painful neuropathy, as well as other features of the disease **(Chap. 411)**. Because only males have a Y chromosome, mutations in genes such as *SRY*, which causes male-to-female sex reversal, or *DAZ* (deleted in azoospermia), which causes abnormalities of spermatogenesis, are unique to males **(Chap. 383)**.

Other diseases are expressed in a sex-limited manner because of the differential function of the gene product in males and females. Activating mutations in the luteinizing hormone receptor cause dominant male-limited precocious puberty in boys **(Chap. 384)**. The phenotype is unique to males because activation of the receptor induces testosterone production in the testis, whereas it is functionally silent in the immature ovary. Biallelic inactivating mutations of the follicle-stimulating hormone (FSH) receptor cause primary ovarian failure in females because the follicles do not develop in the absence of FSH action. In contrast, affected males have a more subtle phenotype, because testosterone production is preserved (allowing sexual maturation) and spermatogenesis is only partially impaired **(Chap. 384)**. In congenital adrenal hyperplasia, most commonly caused by 21-hydroxylase deficiency, cortisol production is impaired and ACTH stimulation of the adrenal gland leads to increased production of androgenic precursors **(Chap. 379)**. In females, the increased androgen level causes ambiguous genitalia, which can be recognized at the time of birth. In males, the diagnosis may be made on the basis of adrenal insufficiency at birth, because the increased adrenal androgen level does not alter sexual differentiation, or later in childhood, because of the development of precocious puberty. Hemochromatosis is more common in males than in females, presumably because of differences in dietary iron intake and losses associated with menstruation and pregnancy in females **(Chap. 407)**.

Chromosomal Disorders *Chromosomal disorders* and the techniques used for their characterization have been discussed in detail in a chapter in previous editions of this textbook. Chromosomal or cytogenetic disorders are caused by numerical (aneuploidy) or structural aberrations (deletions, duplications, translocations, inversions, dicentric and ring chromosomes, Robertsonian translocations) in chromosomes. They occur in about 1% of the general population, in 8% of stillbirths, and in close to 50% of spontaneously aborted fetuses. Indications for cytogenetic and cytogenomic chromosome analyses are summarized in **Table 456-4**. *Contiguous gene syndromes* (e.g., large deletions affecting several genes) have been useful for identifying the location of new disease-causing genes. Because of the variable size of gene deletions in different patients, a systematic comparison of phenotypes and locations of deletion breakpoints allows positions of particular genes to be mapped within the critical genomic region.

Monogenic Mendelian Disorders Monogenic human diseases are frequently referred to as *Mendelian disorders* because they obey

TABLE 456-4 Indications for Cytogenetic and Cytogenomic Analysis across the Lifespan

TIMING OF TESTING	INDICATIONS FOR TESTING
Prenatal	Advanced maternal age
	Abnormalities on ultrasound
	Increased risk for genetic disorder on maternal serum screen
Neonatal and Childhood	Multiple congenital anomalies
	Intellectual disability
	Autism
	Developmental delay
	Failure to thrive
	Short stature
	Disorders of sexual development
	History of familial chromosomal alteration
	Cancer
Adult	Infertility
	Recurrent miscarriage
	Familial cancer

the principles of genetic transmission originally set forth in Gregor Mendel's classic work. The continuously updated OMIM catalogue lists several thousand of these disorders and provides information about the clinical phenotype, molecular basis, allelic variants, and pertinent animal models (Table 456-1). The mode of inheritance for a given phenotypic trait or disease is determined by pedigree analysis. All affected and unaffected individuals in the family are recorded in a pedigree using standard symbols **(Fig. 456-11)**. The principles of allelic segregation, and the transmission of alleles from parents to children, are illustrated in **Fig. 456-12**. One dominant (A) allele and one recessive (a) allele can display three Mendelian modes of inheritance: autosomal dominant, autosomal recessive, and X-linked. About 65% of human monogenic disorders are autosomal dominant, 25% are autosomal recessive, and 5% are X-linked. Genetic testing is now available for many of these disorders and plays an important role in clinical medicine **(Chap. 457)**.

AUTOSOMAL DOMINANT DISORDERS In autosomal dominant disorders, mutations in a single allele are sufficient to cause the disease. In contrast to recessive disorders, in which disease pathogenesis is relatively straightforward because there is a biallelic loss of gene function, dominant disorders can be caused by various disease mechanisms, many of which are unique to the function of the genetic pathway involved. Mechanistically, the mutation may confer constitutive activation (gain-of-function), exert a dominant negative effect, or result in loss-of-function and haploinsufficiency.

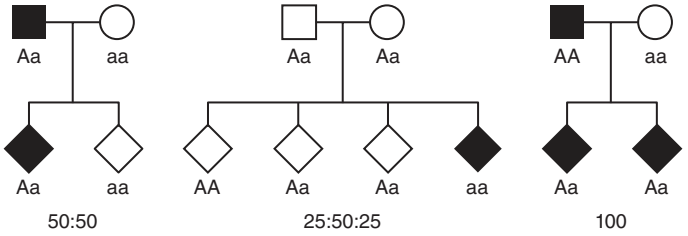

FIGURE 456-12 Segregation of alleles. Segregation of genotypes in the offspring of parents with one dominant (A) and one recessive (a) allele. The distribution of the parental alleles to their offspring depends on the combination present in the parents. Filled symbols = affected individuals.

In autosomal dominant disorders, individuals are affected in successive generations; the disease does not occur in the offspring of unaffected individuals. Males and females are affected with equal frequency because the defective gene resides on one of the 22 autosomes **(Fig. 456-13*A*)**. Autosomal dominant mutations alter one of the two alleles at a given locus. Because the alleles segregate randomly at meiosis, the probability that an offspring will be affected is 50%. Unless there is a new germline mutation, an affected individual has an affected parent. Children with a normal genotype do not transmit the disorder. Due to differences in penetrance or expressivity (see above), the clinical manifestations of autosomal dominant disorders may be variable. Because of these variations, it is sometimes challenging to determine the pattern of inheritance.

It should be recognized, however, that some individuals acquire a mutated gene from an unaffected parent. De novo germline mutations occur more frequently during later cell divisions in gametogenesis, which explains why siblings are rarely affected. As noted before, new germline mutations occur more frequently in fathers of advanced age. For example, the average age of fathers with new germline mutations that cause Marfan's syndrome is ~37 years, whereas fathers who transmit the disease by inheritance have an average age of ~30 years.

AUTOSOMAL RECESSIVE DISORDERS In recessive disorders, the mutated alleles result in a complete or partial loss of function. They frequently involve enzymes in metabolic pathways, receptors, or proteins in signaling cascades. In an autosomal recessive disease, the affected

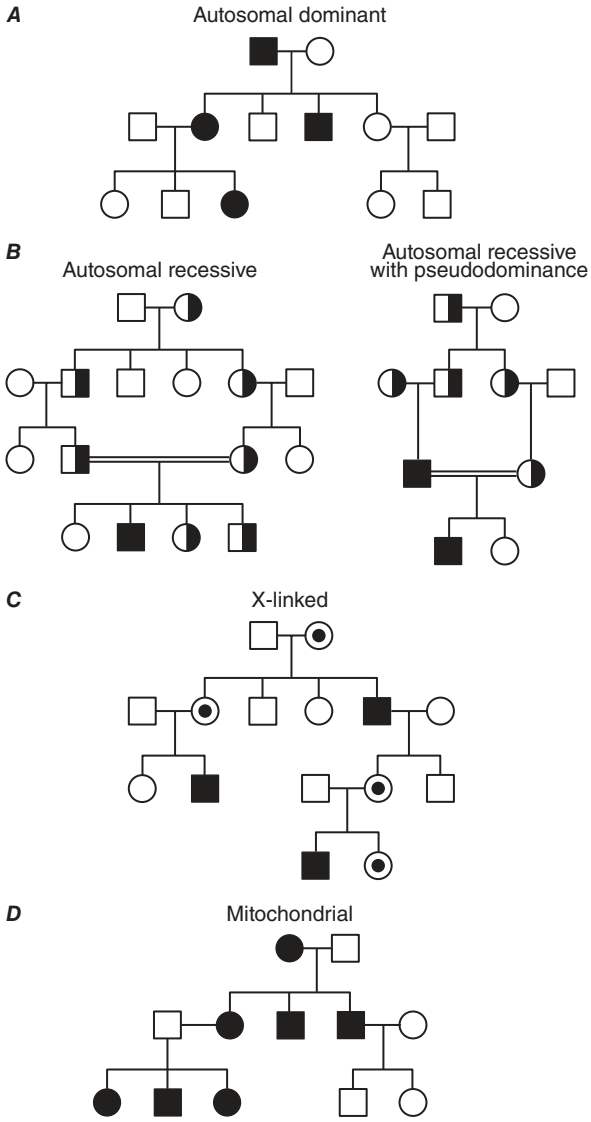

FIGURE 456-13 ***A.*** Dominant, ***B.*** recessive, ***C.*** X-linked, and ***D.*** mitochondrial (matrilinear) inheritance.

individual, who can be of either sex, is a homozygote or compound heterozygote for a single-gene defect. With a few important exceptions, autosomal recessive diseases are rare and often occur in the context of parental consanguinity. The relatively high frequency of certain recessive disorders such as sickle cell anemia, cystic fibrosis, and thalassemia, is partially explained by a selective biologic advantage for the heterozygous state (see below). Although heterozygous carriers of a defective allele are usually clinically normal, they may display subtle differences in phenotype that only become apparent with more precise testing or in the context of certain environmental influences. In sickle cell anemia, for example, heterozygotes are normally asymptomatic. However, in situations of dehydration or diminished oxygen pressure, sickle cell crises can also occur in heterozygotes **(Chap. 94)**.

In most instances, an affected individual is the offspring of heterozygous parents. In this situation, there is a 25% chance that the offspring will have a normal genotype, a 50% probability of a heterozygous state, and a 25% risk of homozygosity for the recessive alleles (**Figs.** 456-10, **456-13*B***). In the case of one unaffected heterozygous and one affected homozygous parent, the probability of disease increases to 50% for each child. In this instance, the pedigree analysis mimics an autosomal dominant mode of inheritance (*pseudodominance*). In contrast to autosomal dominant disorders, new mutations in recessive alleles are rarely manifest because they usually result in an asymptomatic carrier state.

X-LINKED DISORDERS Males have only one X chromosome; consequently, a daughter always inherits her father's X chromosome in addition to one of her mother's two X chromosomes. A son inherits the Y chromosome from his father and one maternal X chromosome. Thus, the characteristic features of X-linked inheritance are (1) the absence of father-to-son transmission, and (2) the fact that all daughters of an affected male are obligate carriers of the mutant allele **(Fig. 456-13*C*)**. The risk of developing disease due to a mutant X-chromosomal gene differs in the two sexes. Because males have only one X chromosome, they are hemizygous for the mutant allele; thus, they are more likely to develop the mutant phenotype, regardless of whether the mutation is dominant or recessive. A female may be either heterozygous or homozygous for the mutant allele, which may be dominant or recessive. The terms *X-linked dominant* or *X-linked recessive* are therefore only applicable to expression of the mutant phenotype in women. In addition, the expression of X-chromosomal genes is influenced by X chromosome inactivation.

Y-LINKED DISORDERS The Y chromosome has a relatively small number of genes. One such gene, the sex-region determining Y factor (*SRY*), which encodes the testis-determining factor (*TDF*), is crucial for normal male development. Normally there is infrequent exchange of sequences on the Y chromosome with the X chromosome. The *SRY* region is adjacent to the pseudoautosomal region, a chromosomal segment on the X and Y chromosomes with a high degree of homology. A crossing-over event occasionally involves the *SRY* region with the distal tip of the X chromosome during meiosis in the male. Translocations can result in XY females with the Y chromosome lacking the *SRY* gene or XX males harboring the *SRY* gene on one of the X chromosomes **(Chap. 383)**. Point mutations in the *SRY* gene may also result in individuals with an XY genotype and an incomplete female phenotype. Most of these mutations occur de novo. Men with oligospermia/azoospermia frequently have microdeletions on the long arm of the Y chromosome that involve one or more of the azoospermia factor (*AZF*) genes.

Exceptions to Simple Mendelian Inheritance Patterns •

MITOCHONDRIAL DISORDERS Mendelian inheritance refers to the transmission of genes encoded by DNA contained in the nuclear chromosomes. In addition, each mitochondrion contains several copies of a small circular chromosome **(Chap. 472)**. The mitochondrial DNA (mtDNA) is ~16.5 kb and encodes transfer and ribosomal RNAs and 13 core proteins that are components of the respiratory chain involved in oxidative phosphorylation and ATP generation. The mitochondrial genome does not recombine and is inherited through the maternal line because sperm does not contribute significant cytoplasmic components to the zygote. A noncoding region of the mitochondrial chromosome, referred to as D-loop, is highly polymorphic. This property, together with the absence of mtDNA recombination, makes it a valuable tool for studies tracing human migration and evolution, and it is also used for specific forensic applications.

Inherited mitochondrial disorders are transmitted in a matrilineal fashion; all children from an affected mother will inherit the disease, but it will not be transmitted from an affected father to his children **(Fig. 456-13*D*)**. Alterations in the mtDNA that involves enzymes required for oxidative phosphorylation lead to reduction of ATP supply, generation of free radicals, and induction of apoptosis. Several syndromic disorders arising from mutations in the mitochondrial genome are known in humans and they affect both protein-coding and tRNA genes. The broad clinical spectrum often involves (cardio) myopathies and encephalopathies because of the high dependence of these tissues on oxidative phosphorylation. The age of onset and the clinical course are highly variable because of the unusual mechanisms of mtDNA transmission, which replicates independently from nuclear DNA. During cell replication, the proportion of wild-type and mutant mitochondria can drift among different cells and tissues. The resulting heterogeneity in the proportion of mitochondria with and without a mutation is referred to as *heteroplasmia* and underlies the phenotypic variability that is characteristic of mitochondrial diseases.

Acquired somatic mutations in mitochondria are thought to be involved in several age-dependent degenerative disorders affecting predominantly muscle and the peripheral and central nervous system (e.g., Alzheimer's and Parkinson's diseases). Establishing that an mtDNA alteration is causal for a clinical phenotype is challenging because of the high degree of polymorphism in mtDNA and the phenotypic variability characteristic of these disorders. Certain pharmacologic treatments may have an impact on mitochondria and/or their function. For example, treatment with the antiretroviral compound azidothymidine (AZT) causes an acquired mitochondrial myopathy through depletion of muscular mtDNA.

MOSAICISM Mosaicism refers to the presence of two or more genetically distinct cell lines in the tissues of an individual. It results from a mutation that occurs during embryonic, fetal, or extrauterine development. The developmental stage at which the mutation arises will determine whether germ cells and/or somatic cells are involved. Chromosomal mosaicism results from nondisjunction at an early embryonic mitotic division, leading to the persistence of more than one cell line, as exemplified by some patients with Turner's syndrome **(Chap. 383)**. Somatic mosaicism is characterized by a patchy distribution of genetically altered somatic cells. The McCune-Albright syndrome, for example, is caused by activating mutations in the stimulatory G protein α (Gsα) that occur early in development **(Chap. 403)**. The clinical phenotype varies depending on the tissue distribution of the mutation; manifestations include ovarian cysts that secrete sex steroids and cause precocious puberty, polyostotic fibrous dysplasia, café-au-lait skin pigmentation, GH–secreting pituitary adenomas, and hypersecreting autonomous thyroid nodules.

X-INACTIVATION, IMPRINTING, AND UNIPARENTAL DISOMY According to traditional Mendelian principles, the parental origin of a mutant gene is irrelevant for the expression of the phenotype. There are, however, important exceptions to this rule. *X-inactivation* prevents the expression of most genes on one of the two X chromosomes in every cell of a female. Gene inactivation through genomic imprinting occurs on selected chromosomal regions of autosomes and leads to inheritable preferential expression of one of the parental alleles. It is of pathophysiologic importance in disorders where the transmission of disease is dependent on the sex of the transmitting parent and, thus, plays an important role in the expression of certain genetic disorders. Two classic examples are the Prader-Willi syndrome and Angelman's syndrome. Prader-Willi syndrome is characterized by diminished fetal activity, obesity, hypotonia, mental retardation, short stature, and hypogonadotropic hypogonadism. Deletions of the paternal copy of the Prader-Willi locus located on the short arm of chromosome 15 result in a contiguous gene syndrome involving missing paternal copies of the *necdin* and *SNRPN* genes, among others. In contrast, patients with

Angelman's syndrome, characterized by mental retardation, seizures, ataxia, and hypotonia, have deletions involving the maternal copy of this region on chromosome 15. These two syndromes may also result from *uniparental disomy*. In this case, the syndromes are not caused by deletions on chromosome 15 but by the inheritance of either two maternal chromosomes (Prader-Willi syndrome) or two paternal chromosomes (Angelman's syndrome). Lastly, the two distinct phenotypes can also be caused by an imprinting defect that impairs the resetting of the imprint during zygote development (defect in the father leads to Prader-Willi syndrome; defect in the mother leads to Angelman's syndrome).

Imprinting and the related phenomenon of allelic exclusion may be more common than currently documented, because it is difficult to examine levels of mRNA expression from the maternal and paternal alleles in specific tissues or in individual cells. Genomic imprinting, or uniparental disomy, is involved in the pathogenesis of several other disorders and malignancies. For example, hydatidiform moles contain a normal number of diploid chromosomes, but they are all of paternal origin. The opposite situation occurs in ovarian teratomata, with 46 chromosomes of maternal origin. Expression of the imprinted gene for insulin-like growth factor II (IGF-II) is involved in the pathogenesis of the cancer-predisposing Beckwith-Wiedemann syndrome (BWS). These children show somatic overgrowth with organomegalies and hemihypertrophy, and they have an increased risk of embryonal malignancies such as Wilms' tumor. Normally, only the paternally derived copy of the *IGF-II* gene is active and the maternal copy is inactive. Imprinting of the *IGF-II* gene is regulated by *H19*, which encodes an RNA transcript that is not translated into protein. Disruption or lack of *H19* methylation leads to a relaxation of *IGF-II* imprinting and expression of both alleles. Alterations of the epigenome through gain and loss of DNA methylation, as well as altered histone modifications, play an important role in the pathogenesis of malignancies.

SOMATIC MUTATIONS Cancer can be considered a genetic disease at the cellular level **(Chap. 67)**. Cancers are monoclonal in origin, indicating that they have arisen from a single precursor cell with one or several mutations in genes controlling growth (proliferation or apoptosis) and/or differentiation. These acquired somatic mutations are restricted to the tumor and its metastases and are not found in the surrounding normal tissue. The molecular alterations include dominant gain-of-function mutations in oncogenes, recessive loss-of-function mutations in tumor-suppressor genes and DNA repair genes, gene amplification, and chromosome rearrangements. Rarely, a single mutation in certain genes may be sufficient to transform a normal cell into a malignant cell. In most cancers, however, the development of a malignant phenotype requires several genetic alterations for the gradual progression from a normal cell to a cancerous cell, a phenomenon termed *multistep carcinogenesis*. Genome-wide analyses of cancers using deep sequencing often reveal somatic rearrangements resulting in fusion genes and mutations in multiple genes **(Fig. 456-14)**. Comprehensive sequence analyses provide further insight into genetic heterogeneity within malignancies; these include intratumoral heterogeneity among the cells of the primary tumor, intermetastatic and intrametastatic heterogeneity, and interpatient differences. These analyses further support the notion of cancer as an ongoing process of clonal evolution, in which successive rounds of clonal selection within the primary tumor and metastatic lesions result in diverse genetic and epigenetic alterations that require targeted (personalized) therapies (precision medicine). The heterogeneity of mutations within a tumor can also lead to resistance to target therapies because cells with mutations that are resistant to the therapy, even if they are a minor part of the tumor population, will be selected as the more sensitive cells are killed. Most human tumors express telomerase, an enzyme formed of a protein and an RNA component, which adds telomere repeats at the ends of chromosomes during replication. This mechanism impedes shortening of the telomeres, which is associated with senescence in normal cells and is associated with enhanced replicative capacity in cancer cells. Telomerase inhibitors provide a strategy for treating advanced human cancers.

In many cancer syndromes, there is frequently an inherited *predisposition* to tumor formation. In these instances, a germline mutation is inherited in an autosomal dominant fashion inactivating one allele of an autosomal tumor-suppressor gene. If the second allele is inactivated by a somatic mutation or by epigenetic silencing in a given cell, this will lead to neoplastic growth (Knudson two-hit model). Thus, the defective allele in the germline is transmitted in a dominant mode, although tumorigenesis results from a biallelic loss of the tumor-suppressor gene in an affected tissue. The classic example to illustrate this phenomenon is retinoblastoma, which can occur as a sporadic or hereditary tumor. In sporadic retinoblastoma, both copies of the retinoblastoma (*RB*) gene are inactivated through two somatic events. In hereditary retinoblastoma, one mutated or deleted *RB* allele is inherited in an autosomal

TABLE 456-5 Selected Trinucleotide Repeat Disorders

DISEASE	LOCUS	REPEAT	TRIPLET LENGTH (NORMAL/DISEASE)	INHERITANCE	GENE PRODUCT
X-chromosomal spinobulbar muscular atrophy (SBMA)	Xq11-q12	CAG	11–34/40–62	XR	Androgen receptor
Fragile X syndrome (FRAXA)	Xq27.3	CGG	6–50/200–300	XR	FMR-1 protein
Fragile X syndrome (FRAXE)	Xq28	GCC	6–25/>200	XR	FMR-2 protein
Dystrophia myotonica (DM)	19q13.2-q13.3	CTG	5–30/200–1000	AD, variable penetrance	Myotonin protein kinase
Huntington's disease (HD)	4p16.3	CAG	6–34/37–180	AD	Huntingtin
Spinocerebellar ataxia type 1 (SCA1)	6p21.3-21.2	CAG	6–39/40–88	AD	Ataxin 1
Spinocerebellar ataxia type 2 (SCA2)	12q24.1	CAG	15–31/34–400	AD	Ataxin 2
Spinocerebellar ataxia type 3 (SCA3); Machado-Joseph disease (MD)	14q21	CAG	13–36/55–86	AD	Ataxin 3
Spinocerebellar ataxia type 6 (SCA6, CACNAIA)	19p13.1-13.2	CAG	4–16/20–33	AD	Alpha 1A voltage-dependent L-type calcium channel
Spinocerebellar ataxia type 7 (SCA7)	3p21.1-p12	CAG	4–19/37 to >300	AD	Ataxin 7
Spinocerebellar ataxia type 12 (SCA12)	5q31	CAG	6–26/66–78	AD	Protein phosphatase 2A
Dentatorubral pallidoluysian atrophy (DRPLA)	12p	CAG	7–23/49–75	AD	Atrophin 1
Friedreich's ataxia (FRDA1)	9q13-21	GAA	7–22/200–900	AR	Frataxin

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; XR, X-linked recessive.

dominant manner and the second allele is inactivated by a subsequent somatic mutation. This two-hit model applies to other inherited cancer syndromes such as MEN 1 **(Chap. 381)** and neurofibromatosis type 2 **(Chap. 86)**. In contrast, in the autosomal dominant MEN2 syndrome, the predisposition for tumor formation in various organs is caused by a gain-of-function mutation in a single allele of the *RET* gene **(Chap. 381)**.

NUCLEOTIDE REPEAT EXPANSION DISORDERS Several diseases are associated with an increase in the number of nucleotide repeats above a certain threshold **(Table 456-5)**. The repeats are sometimes located within the coding region of the genes, as in Huntington's disease or the X-linked form of spinal and bulbar muscular atrophy (SBMA; Kennedy's syndrome). In other instances, the repeats probably alter gene regulatory sequences. If an expansion is present, the DNA fragment is unstable and tends to expand further during cell division. The length of the nucleotide repeat often correlates with the severity of the disease. When repeat length increases from one generation to the next, disease manifestations may worsen or be observed at an earlier age; this phenomenon is referred to as *anticipation*. In Huntington's disease, for example, there is a correlation between age of onset and length of the triplet codon expansion **(Chap. 417)**. Anticipation has also been documented in other diseases caused by dynamic mutations in trinucleotide repeats (Table 456-5). The repeat number may also vary in a tissue-specific manner. In myotonic dystrophy, the CTG repeat may be tenfold greater in muscle tissue than in lymphocytes **(Chap. 441)**.

Complex Genetic Disorders

The expression of many common diseases such as cardiovascular disease, hypertension, diabetes, asthma, psychiatric disorders, and certain cancers is determined by a combination of genetic background, environmental factors, and lifestyle. A trait is called *polygenic* if multiple genes contribute to the phenotype or *multifactorial* if multiple genes are assumed to interact with environmental factors. Genetic models for these complex traits need to account for genetic heterogeneity and interactions with other genes and the environment. Complex genetic traits may be influenced by modifier genes that are not linked to the main gene involved in the pathogenesis of the trait. This type of gene-gene interaction, or *epistasis*, plays an important role in polygenic traits that require the simultaneous presence of variations in multiple genes to result in a pathologic phenotype.

Type 2 diabetes mellitus provides a paradigm for considering a multifactorial disorder, because genetic, nutritional, and lifestyle factors are intimately interrelated in disease pathogenesis **(Table 456-6) (Chap. 396)**. The identification of genetic variations and environmental factors that either predispose to or protect against disease is essential for predicting disease risk, designing preventive strategies, and developing novel therapeutic approaches. The study of rare monogenic diseases may provide insight into some of the genetic and molecular mechanisms important in the pathogenesis of complex diseases. For example, the identification of the genes causing monogenic forms of permanent neonatal diabetes mellitus or maturity-onset diabetes defined them as *candidate genes* in the pathogenesis of diabetes mellitus type 2 (Tables 456-2 and 456-6) **(Fig. 456-15)**. Genome scans have identified numerous genes and loci that may be associated with susceptibility to development of diabetes mellitus in certain populations **(Fig. 456-16)**. Efforts to identify susceptibility genes require very large sample sizes, and positive results may depend on ethnicity, ascertainment criteria, and statistical analysis. Association studies analyzing the potential influence of (biologically functional) SNPs and SNP haplotypes on a particular phenotype have revealed new insights into the genes involved in the pathogenesis of these common disorders. Large variants ([micro]deletions, duplications, and inversions) present in the human population also contribute to the pathogenesis of complex disorders, but their contributions remain poorly understood.

Linkage and Association Studies

There are two primary strategies for mapping genes that cause or increase susceptibility to human disease: (1) classic linkage can be performed based on a known genetic model or, when the model is unknown, by studying pairs of affected relatives; or (2) disease genes can be mapped using allelic association studies **(Table 456-7)**.

GENETIC LINKAGE *Genetic linkage* refers to the fact that genes are physically connected, or linked, to one another along the chromosomes. Two fundamental principles are essential for understanding the concept of linkage: (1) when two genes are close together on a chromosome, they are usually transmitted together, unless a recombination event separates them (Figs. 456-6); and (2) the odds of a crossover, or recombination event, between two linked genes is proportional to the distance that separates them. Thus, genes that are farther apart are more likely to undergo a recombination event than genes that are very close together. The detection of chromosomal loci that segregate with a disease by linkage can be used to identify the gene responsible for the disease (*positional cloning*) and to predict the odds of disease gene transmission in genetic counseling.

Polymorphic variants are essential for linkage studies because they provide a means to distinguish the maternal and paternal chromosomes in an individual. On average, 1 out of every 1000 bp varies from one person to the next. Although this degree of variation seems low (99.9% identical), it means that >3 million sequence differences exist

TABLE 456-6 Genes and Loci Involved in Mono- and Polygenic Forms of Diabetes

DISORDER	GENES OR SUSCEPTIBILITY LOCUS	CHROMOSOMAL LOCATION	OTHER FACTORS
Monogenic permanent neonatal diabetes mellitus	*KCNJ11* (inwardly rectifying potassium channelKir6.2)	11p15.1	AD
	GCK (glucokinase)	7p15-p13	AR
	INS (insulin)	11p15.5	AR, hyperproinsulinemia
	ABCC8 (ATP-binding cassette, subfamily c, member 8; sulfonylurea receptor)	11p15.1	AD or AR

between any two unrelated individuals and the probability that the sequence at such loci will differ on the two homologous chromosomes is high (often >70–90%). These sequence variations include variable number of tandem repeats (VNTRs), short tandem repeats (STRs), and SNPs. Most STRs, also called *polymorphic microsatellite markers*, consist of di-, tri-, or tetranucleotide repeats that can be characterized readily using the polymerase chain reaction (PCR). Characterization of SNPs, using DNA chips or beads, permits comprehensive analyses of genetic variation, linkage, and association studies. Although these sequence variations often have no apparent functional consequences, they provide much of the basis for variation in genetic traits.

In order to identify a chromosomal locus that segregates with a disease, it is necessary to characterize polymorphic DNA markers from affected and unaffected individuals of one or several pedigrees. One can then assess whether certain marker alleles cosegregate with the disease. Markers that are closest to the disease gene are less likely to undergo recombination events and therefore receive a higher linkage score. Linkage is expressed as a lod (logarithm of odds) score—the ratio of the probability that the disease and marker loci are linked rather than unlinked. Lod scores of +3 (1000:1) are generally accepted as supporting linkage, whereas a score of –2 is consistent with the absence of linkage.

ALLELIC ASSOCIATION, LINKAGE DISEQUILIBRIUM, AND HAPLOTYPES

Allelic association refers to a situation in which the frequency of an allele is significantly increased or decreased in individuals affected by a particular disease in comparison to controls. Linkage and association differ in several aspects. Genetic linkage is demonstrable in families or sibships. Association studies, on the other hand, compare a population of affected individuals with a control population. Association studies can be performed as case-control studies that include unrelated affected individuals and matched controls or as family-based studies that compare the frequencies of alleles transmitted or not transmitted to affected children.

Allelic association studies are particularly useful for identifying susceptibility genes in complex diseases. When alleles at two loci occur more frequently *in combination* than would be predicted (based on known allele frequencies and recombination fractions), they are said to be in *linkage disequilibrium*. Evidence for linkage disequilibrium can be helpful in mapping disease genes because it suggests that the two loci are tightly linked.

Detecting the genetic factors contributing to the pathogenesis of common complex disorders is challenging. In many instances, these are low-penetrance alleles (e.g., variations that individually have a subtle effect on disease development, and they can only be identified by unbiased GWAS) (Catalog of published Genome-Wide Association

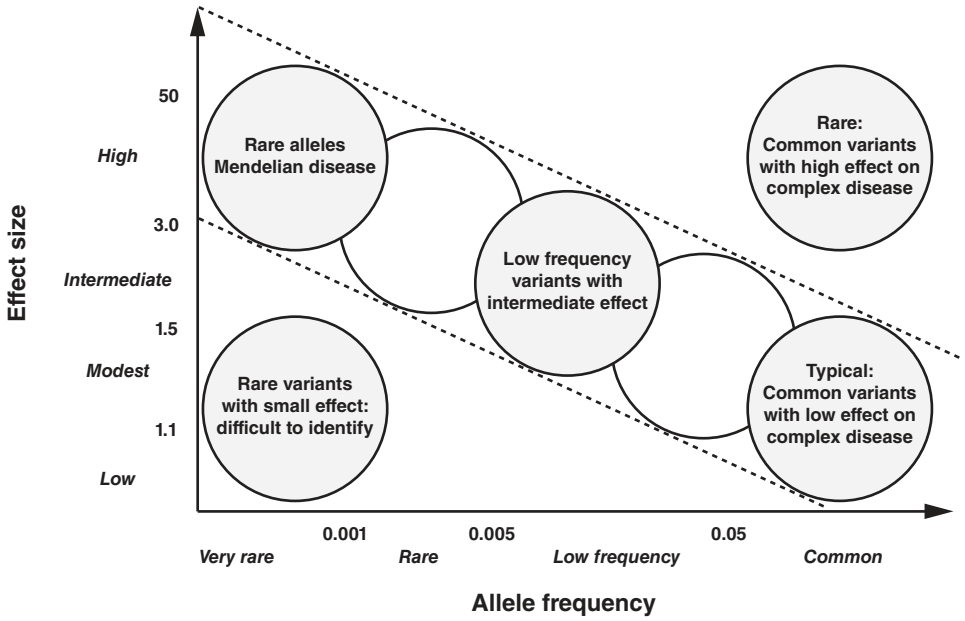

FIGURE 456-15 Relationship between allele frequency and effect size in monogenic and polygenic disorders. In classic Mendelian disorders, the allele frequency is typically low but has a high impact (single gene disorder). This contrasts with polygenic disorders that require the combination of multiple low impact alleles that are frequently quite common in the general population.

Studies; Table 456-1) (Fig. 456-16). Most variants occur in noncoding or regulatory sequences but do not alter protein structure. The analysis of complex disorders is further complicated by ethnic differences in disease prevalence, differences in allele frequencies in known susceptibility genes among different populations, locus and allelic heterogeneity, gene-gene and gene-environment interactions, and the possibility of phenocopies. Catalogues of human variation and genotype data (HapMap, International Genome Sample Resource) are greatly facilitating GWAS for the characterization of complex disorders. Adjacent SNPs are inherited together as blocks, and these blocks can be identified by genotyping selected marker SNPs, so-called *Tag SNPs*, thereby reducing cost and workload (Fig. 456-4). The availability of this information permits the characterization of a limited number of SNPs to identify the set of haplotypes present in an individual (e.g., in cases and controls). This, in turn, permits performing GWAS by searching for associations of certain haplotypes with a disease phenotype of interest, an essential step for unraveling the genetic factors contributing to complex disorders.

POPULATION GENETICS In population genetics, the focus changes from alterations in an individual's genome to the distribution pattern of different genotypes in the population. In a case where there are only two alleles, A and a, the frequency of the genotypes will be $p^2 + 2pq + q^2 = 1$, with p^2 corresponding to the frequency of AA, $2pq$ to the frequency of Aa, and q^2 to aa. When the frequency of an allele is known, the frequency of the genotype can be calculated. Alternatively, one can determine an allele frequency if the genotype frequency has been determined.

Allele frequencies vary among ethnic groups and geographic regions. For example, heterozygous mutations in the *CFTR* gene are relatively common in populations of European origin but are rare in the African population. Allele frequencies may vary because certain allelic variants confer a selective advantage. For example, heterozygotes for the sickle cell mutation, which is particularly common in West Africa, are more resistant to malarial infection because the erythrocytes of heterozygotes provide a less favorable environment for *Plasmodium* parasites. Although homozygosity for the sickle cell mutation is associated with severe anemia and sickle crises, heterozygotes have a higher probability of survival because of the reduced morbidity and mortality from malaria; this phenomenon has led to an increased frequency of the mutant allele. Recessive conditions are more prevalent in geographically isolated populations because of the more restricted gene pool.

APPROACH TO THE PATIENT

Inherited Disorders

For the practicing clinician, the family history remains an essential step in recognizing the possibility of a hereditary predisposition to disease. When taking the history, it is useful to draw a detailed pedigree of the first-degree relatives (e.g., parents, siblings, and children), because they share 50% of genes with the patient. Standard symbols for pedigrees are depicted in Fig. 456-11. The family history should include information about ethnic background, age, health status, and deaths, including infants. Next, the physician should explore whether there is a family history of the same or related illnesses to the current problem. An inquiry focused on commonly occurring disorders such as cancers, heart disease, and diabetes mellitus should follow. Because of the possibility of age-dependent expressivity and penetrance, the family history will need intermittent updating. If the findings suggest a genetic disorder, the clinician should assess whether some of the patient's relatives may be at risk of carrying or transmitting the disease. In this circumstance, it is useful to confirm and extend the pedigree based on input from several family members. This information may form the basis for genetic counseling, carrier detection, early intervention, and disease prevention in relatives of the index patient (Chap. 457).

In instances where a diagnosis at the molecular level may be relevant, it is important to identify an appropriate laboratory that can perform the appropriate test. Genetic testing is available for a large number of monogenic disorders through commercial laboratories. For uncommon disorders, the test may only be performed in a specialized research laboratory. Approved laboratories offering testing for inherited disorders can be identified in continuously updated online resources (e.g., GeneTests; Table 456-1). If genetic testing is considered, the patient and the family should be counseled about the potential implications of positive results, including psychological distress and the possibility of discrimination. The patient or caretakers should be informed about the meaning of a negative result, technical limitations, and the possibility of false-negative and inconclusive results. For these reasons, genetic testing should only be performed after obtaining *informed consent*. Published ethical guidelines address the specific aspects that should be considered when testing children and adolescents. Genetic testing should usually be limited

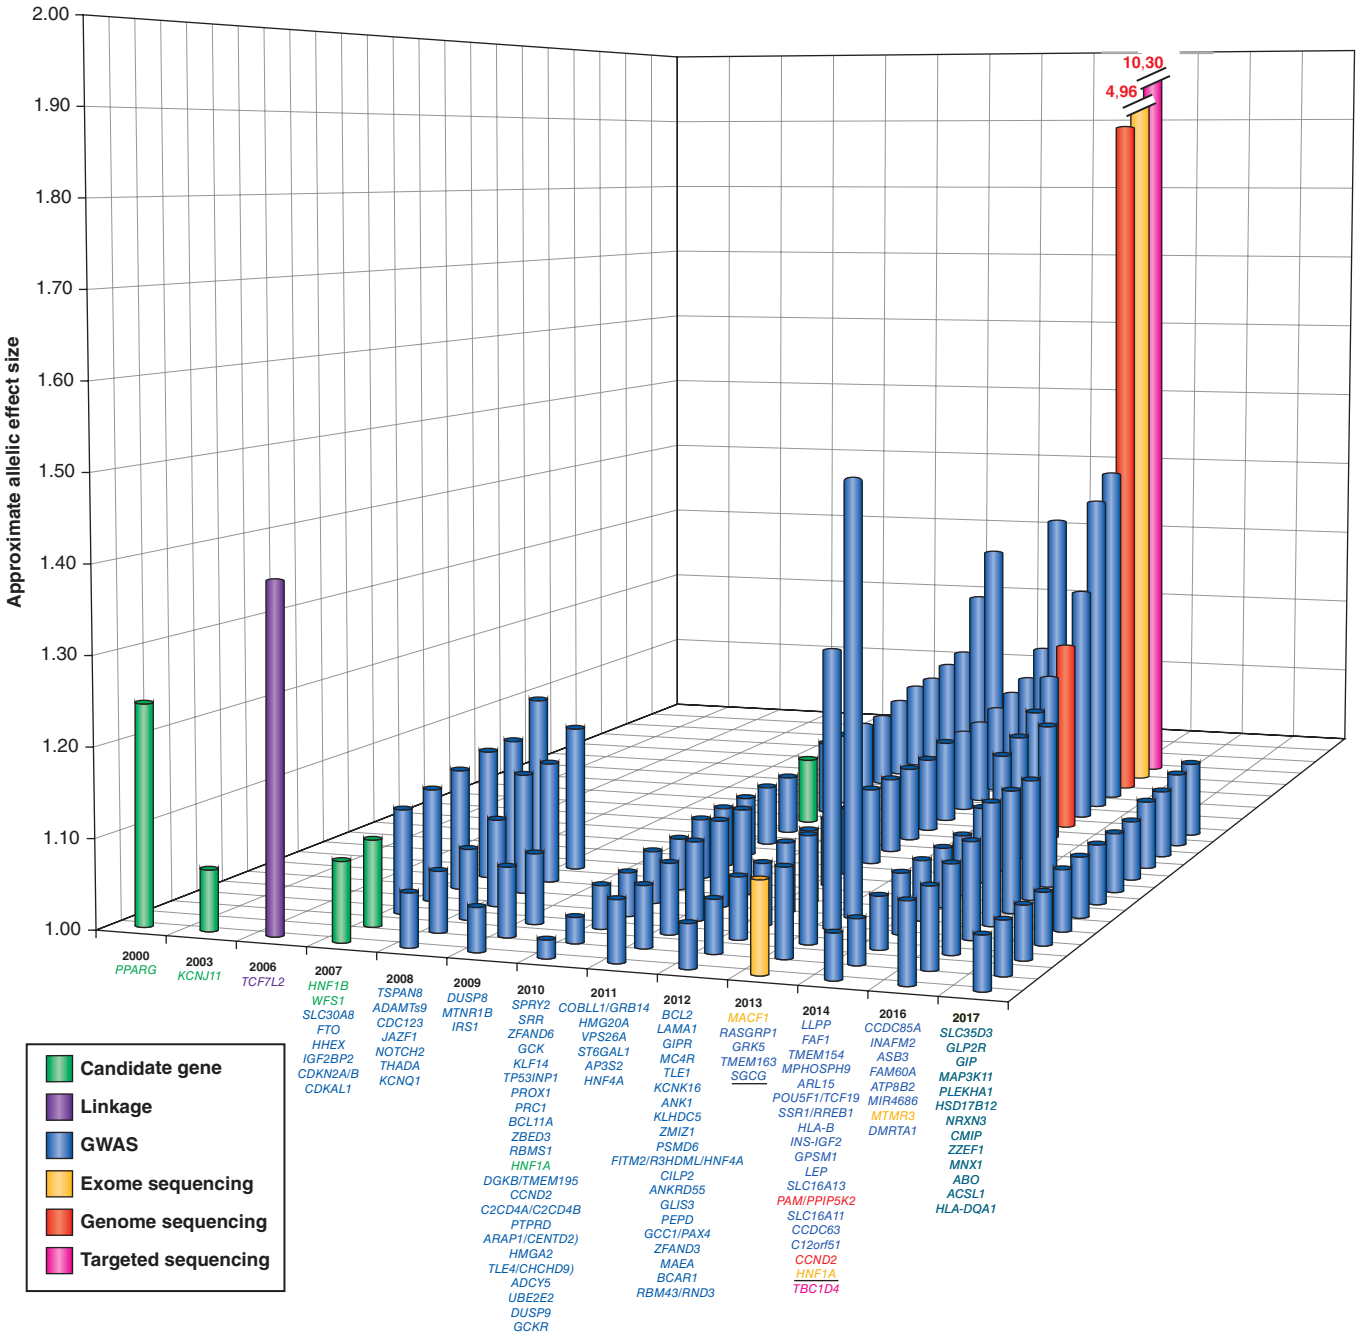

FIGURE 456-16 Loci and genes associated with diabetes mellitus type 2. Loci are listed by year of identification, and the color indicates discovery method. Gene names indicate the locus and does not necessarily imply that the gene itself is causally involved. Approximate allelic effect sizes were either derived from the discovery cohort or, if available, from the DIAGRAM (Diabetes Genetics Replication and Meta-analysis consortium) European ancestry meta-analysis and the Asian ancestry meta-analysis. Gene names that are underlined denote identification in population isolates. *(The data have been graciously provided by Dr. Miriam Udler and Dr. Jose Florez, Harvard Medical School, Boston.)*

to situations in which the results may have an impact on medical management.

IDENTIFYING THE DISEASE-CAUSING GENE

Precision medicine aims to enhance the quality of medical care through the use of genotypic analysis (DNA testing) to identify genetic predisposition to disease, to select more specific pharmacotherapy, and to design individualized medical care based on genotype. Genotype can be deduced by analysis of protein (e.g., hemoglobin, apoprotein E), mRNA, or DNA. However, technologic advances have made DNA analysis particularly useful because it can be readily applied.

DNA testing is performed by mutational analysis or linkage studies in individuals at risk for a genetic disorder known to be present in a family. Mass screening programs require tests of high sensitivity and specificity to be cost-effective. Prerequisites for the success of genetic screening programs include the following: that the disorder is potentially serious; that it can be influenced at a presymptomatic stage by changes in behavior, diet, and/or pharmaceutical manipulations; and that the screening does not result in any harm or discrimination. Screening in Jewish populations for the autosomal recessive neurodegenerative storage disease Tay-Sachs has reduced the number of affected individuals. In contrast, screening for sickle cell trait/disease in African Americans has led to unanticipated problems of discrimination by health insurers and employers. Mass screening programs harbor additional potential problems. For example, screening for the most common genetic alteration in cystic fibrosis, the ΔF508 mutation with a frequency of ~70% in northern Europe, is feasible and seems to be effective.

TABLE 456-7 Genetic Approaches for Identifying Disease Genes

METHOD	INDICATIONS AND ADVANTAGES	LIMITATIONS
Linkage Studies		
Classical linkage analysis (parametric methods)	Analysis of monogenic traits Suitable for genome scan Control population not required Useful for multifactorial disorders in isolated populations	Difficult to collect large informative pedigrees Difficult to obtain sufficient statistical power for complex traits
Allele-sharing methods (nonparametric methods)	Suitable for identification of susceptibility genes in polygenic and multifactorial disorders	Difficult to collect sufficient number of subjects
Affected sib and relative pair analyses	Suitable for genome scan	Difficult to obtain sufficient statistical power for complex traits
Sib pair analysis	Control population not required if allele frequencies are known Statistical power can be increased by including parents and relatives	Reduced power compared to classical linkage, but not sensitive to specification of genetic mode
Association Studies		
Case-control studies	Suitable for identification of susceptibility genes in polygenic and multifactorial disorders	Requires large sample size and matched control population
Linkage disequilibrium	Suitable for testing specific allelic variants of known candidate loci	False-positive results in the absence of suitable control population
Transmission disequilibrium test (TDT)	Facilitated by comprehensive catalogs of genotypes and variants	Candidate gene approach does not permit detection of novel genes and pathways
Whole-genome association studies	Does not necessarily need relatives	Susceptibility genes can vary among different populations
Next-Generations Sequencing Technologies		
Whole exome or genome sequencing	Unbiased approach, analysis can be performed without reference sequences from parents or siblings	Requires appropriate bioinformatics, may have low sensitivity if CNV analysis is not included, detects numerous VUS, can lead to the detection of unrelated deleterious alleles
Targeted sequencing of gene panels	Captures multiple candidate genes and loci with hybridization techniques followed by deep sequencing	Permits analyses of multiple candidate genes in parallel. Facilitates molecular characterization of disorders with locus heterogeneity.

Abbreviations: CNV, copy number variation; GWAS, genome-wide association study; VUS, variants of unknown significance.

One has to keep in mind, however, that there is pronounced allelic heterogeneity and that the disease can be caused by about 2000 other mutations. The search for these less common mutations would substantially increase costs, but not the effectiveness of the screening program as a whole. Next-generation genome sequencing permits comprehensive and cost-effective mutational analyses after selective enrichment of candidate genes. For example, tests that sequence all the common genes causing hereditary deafness or hereditary pheochromocytomas are commercially available. Occupational screening programs aim to detect individuals with increased risk for certain professional activities (e.g., α_1 antitrypsin deficiency and smoke or dust exposure). Integrating genomic data into electronic medical records is evolving and can provide significant decision support at the point of care, for example, by providing the clinician with genomic data and decision algorithms for the prescription of drugs that are subject to pharmacogenetic influences.

Mutational Analyses DNA sequence analysis is now widely used as a diagnostic tool and has significantly enhanced diagnostic accuracy. It is used for determining carrier status and for prenatal testing in monogenic disorders. Numerous techniques, discussed in previous versions of this chapter, are available for the detection of mutations. In a very broad sense, one can distinguish between techniques that allow for screening of known mutations (screening mode) or techniques that definitively characterize mutations. Analyses of large alterations in the genome are possible using classic methods such as karyotype analysis, cytogenetics, fluorescent in situ hybridization (FISH), as well as more sensitive array- or bead-based techniques that search for multiple single exon deletions or duplications.

More discrete sequence alterations rely heavily on the use of PCR, which allows rapid gene amplification and analysis. Moreover, PCR makes it possible to perform genetic testing and mutational analysis with small amounts of DNA extracted from leukocytes or even from single cells, buccal cells, or hair roots. DNA sequencing can be performed directly on PCR products or on fragments cloned into plasmid vectors amplified in bacterial host cells. Sequencing of the whole genome, exome, selected chromosomes, or sequencing of numerous candidate genes in a single run, is now possible with next-generation sequencing platforms and has entered the clinical realm. Genomic tests are also widely used for the detection of pathogens and for the identification of viral or bacterial sequence variations. The integration of genomic tests into clinical medicine is, however, associated with a number of ongoing challenges related to costs, variable sensitivities of the tests, bioinformatics analyses, storage and sharing of data, and the difficulty of interpreting all genetic variants identified with comprehensive testing. The discovery of incidental (or secondary) findings that are unrelated to the indication for the sequencing analysis but indicators of other disorders of potential relevance for patient care can pose a difficult ethical dilemma. It can lead to the detection of undiagnosed medically actionable genetic conditions, but can also reveal deleterious mutations that cannot be influenced, as numerous sequence variants are of unknown significance.

A general algorithm for the approach to mutational analysis is outlined in Fig. 456-17. The importance of a detailed clinical phenotype cannot be overemphasized. This is the step where one should also consider the possibility of genetic heterogeneity and phenocopies. If obvious candidate genes are suggested by the phenotype, they can be analyzed directly. After identification of a mutation, it is essential to demonstrate that it segregates with the phenotype. The functional characterization of novel mutations is labor intensive and may require analyses in vitro or in transgenic models in order to document the relevance of the genetic alteration.

Prenatal diagnosis of numerous genetic diseases in instances with a high risk for certain disorders is now possible by direct DNA analysis. *Amniocentesis* involves the removal of a small amount of amniotic fluid, usually at 16 weeks of gestation. Cells can be collected and submitted for karyotype analyses, FISH, and mutational analysis of selected genes Table 456-4). The main indications for amniocentesis include advanced maternal age (>35 years), presence of an abnormality of the fetus on ultrasound examination, an abnormal serum "quad" test (α-fetoprotein, β human chorionic gonadotropin, inhibin-A, and unconjugated estriol), a family history of chromosomal abnormalities, or a Mendelian disorder amenable to genetic testing.

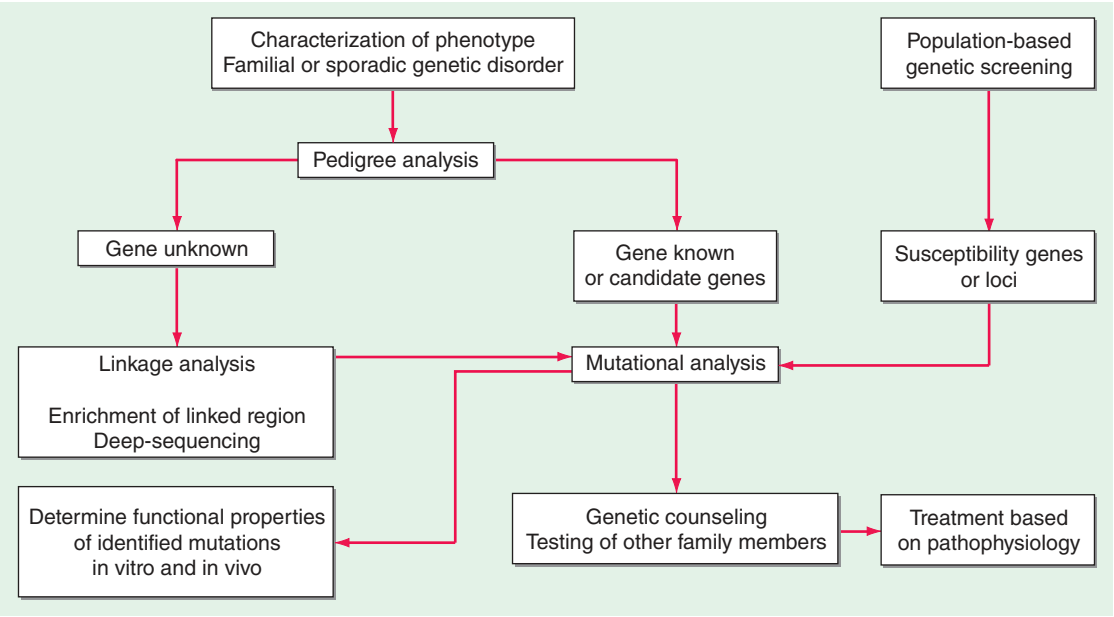

FIGURE 456-17 Approach to genetic disease.

Prenatal diagnosis can also be performed by *chorionic villus sampling* (CVS), in which a small amount of the chorion is removed by a transcervical or transabdominal biopsy. Chromosomes and DNA obtained from these cells can be submitted for cytogenetic and mutational analyses. CVS can be performed earlier in gestation (weeks 9–12) than amniocentesis, an aspect that may be of relevance when termination of pregnancy is a consideration. Later in pregnancy, beginning at about 18 weeks of gestation, percutaneous umbilical blood sampling (PUBS) permits collection of fetal blood for lymphocyte culture and analysis. These approaches enable screening for clinically relevant and deleterious alleles inherited from the parents, as well as for de novo germline mutations, and they may have the potential to change the diagnosis of genetic disorders in the prenatal setting. Although genomic sequencing of fetal DNA circulating in the bloodstream of the mother has been achieved, it is not commonly used for non-invasive prenatal testing.

In combination with in vitro fertilization (IVF) techniques, it is possible to perform genetic diagnoses in a single cell removed from the four- to eight-cell embryo or to analyze the first polar body from an oocyte. Preconceptual diagnosis thereby avoids therapeutic abortions but is costly and labor intensive. It should be emphasized that excluding a specific disorder by any of these approaches is never equivalent to the assurance of having a normal child. Postnatal indications for cytogenetic analyses in infants or children include multiple congenital anomalies, suspicion of a known cytogenetic syndrome, developmental delay, dysmorphic features, autism, short stature and disorders of sexual development, among others (Table 456-4).

Mutations in certain cancer susceptibility genes such as *BRCA1* and *BRCA2* may identify individuals with an increased risk for the development of malignancies and result in risk-reducing interventions. The detection of cytogenetic alterations and mutations is an important diagnostic and prognostic tool in leukemias and somatic mutational analysis is transforming oncology by providing diagnostic and prognostic information, and it informs the choice of targeted therapies. However, the cancer may recur due to treatment resistance of subclones due to the continuously evolving genomic landscape. The demonstration of the presence or absence of mutations and polymorphisms is also relevant for the rapidly evolving field of pharmacogenomics, including the identification of differences in drug treatment response or metabolism as a function of genetic background. For example, the thiopurine drugs 6-mercaptopurine and azathioprine are commonly used cytotoxic and immunosuppressive agents. They are metabolized by thiopurine methyltransferase (TPMT), an enzyme with variable activity associated with genetic polymorphisms in 10% of whites and complete deficiency in about 1 in 300 individuals. Patients with intermediate or deficient TPMT activity are at risk for excessive toxicity, including fatal myelosuppression. Characterization of these polymorphisms allows mercaptopurine doses to be modified based on TPMT genotype. Pharmacogenomics may increasingly permit individualized drug therapy, improve drug effectiveness, reduce adverse side effects, and provide cost-effective pharmaceutical care **(Chap. 64)**.

ETHICAL ISSUES

Determination of the association of genetic defects with disease, comprehensive data of an individual's genome, and studies of genetic variation raise many ethical and legal issues. Genetic information is generally regarded as sensitive information that should not be readily accessible without explicit consent (*genetic privacy*). The disclosure of genetic information may risk possible discrimination by insurers or employers. The scientific components of the Human Genome Project have been paralleled by efforts to examine ethical, social, and legal implications. An important milestone emerging from these endeavors consists in the Genetic Information Nondiscrimination Act (GINA), signed into law in 2008, which aims to protect asymptomatic individuals against the misuse of genetic information for health insurance and employment. It does not, however, protect the symptomatic individual. Provisions of the U.S. Patient Protection and Affordable Care Act, effective in 2014, have, in part, filled this gap and prohibit exclusion from, or termination of, health insurance based on personal health status. Potential threats to the maintenance of genetic privacy consist in the emerging integration of genomic data into electronic medical records, compelled disclosures of health records, and direct-to-consumer genetic testing.

It is widely accepted that identifying disease-causing genes can lead to improvements in diagnosis, treatment, and prevention. However, the information gleaned from genotypic results can have quite different impacts, depending on the availability of strategies to modify the course of disease. For example, the identification of mutations that cause MEN 2 or hemochromatosis allows specific interventions for affected family members. On the other hand, at present, the identification of an Alzheimer's or Huntington's disease gene does not currently alter therapy and outcomes. Most genetic disorders are likely to fall into an intermediate category where the

opportunity for prevention or treatment is significant but limited. However, the progress in this area is unpredictable, as underscored by the finding that angiotensin II receptor blockers may slow disease progression in Marfan's syndrome. Genetic test results can generate anxiety in affected individuals and family members. Comprehensive sequence analyses are particularly challenging because most individuals can be expected to harbor several serious recessive gene mutations. Moreover, the sensitivity of comprehensive sequence analyses are not always greater, for example, if CNV analysis is not integrated, but can be associated with higher costs.

The impact of genetic testing on health care costs remain unclear. It does vary among disorders and depends on the availability of effective therapeutic modalities. A significant problem arises from the marketing of genetic testing directly to consumers by commercial companies. The validity of these tests is, in part, not well defined, and there are persisting concerns about the lack of appropriate regulatory oversight, the accuracy and confidentiality of genetic information, the availability of counseling, and the handling of these results.

Many issues raised by the genome project are familiar, in principle, to medical practitioners. For example, an asymptomatic patient with increased low-density lipoprotein (LDL) cholesterol, high blood pressure, or a strong family history of early myocardial infarction is known to be at increased risk of coronary heart disease. In such cases, it is clear that the identification of risk factors and an appropriate intervention are beneficial. Likewise, patients with phenylketonuria, cystic fibrosis, or sickle cell anemia are often identified as having a genetic disease early in life. These precedents can be helpful for adapting policies that relate to genetic information. We can anticipate similar efforts, whether based on genotypes or other markers of genetic predisposition, to be applied to many disorders. One confounding aspect of the rapid expansion of information is that our ability to make clinical decisions often lags behind initial insights into genetic mechanisms of disease. For example, when genes that predispose to breast cancer such as *BRCA1* are described, they generate tremendous public interest in the potential to predict disease, but many years of clinical research are still required to rigorously establish genotype and phenotype correlations.

Genomics may contribute to improvements in global health by providing a better understanding of pathogens and diagnostics, and through contributions to drug development. There is, however, ongoing concern about the development of a "genomics divide" because of the costs associated with these developments and uncertainty as to whether these advances will be accessible to the populations of developing countries faced with pressing health needs associated with poverty, infectious diseases, and the relative lack of essential infrastructure. The World Health Organization has summarized these issues and inequities surrounding genomic medicine in a detailed report titled "Genomics and World Health."

Whether related to informed consent, participation in research, or the management of a genetic disorder that affects an individual or his or her family, there is a great need for more information about fundamental principles of genetics. The pervasive nature of the role of genetics in medicine makes it important for physicians and other health care professionals to become more informed about genetics and to provide advice and counseling in conjunction with trained genetic counselors **(Chap. 457)**. The application of screening and prevention strategies does therefore require continuing patient and physician education, changes in health care financing, and legislation to protect patient's rights.

Acknowledgment

Selected sections and Table 456-4 have been integrated from the chapter on Chromosome Disorders by Dr. Nancy B. Spinner and Dr. Laura K. Conlin, published in the 19th edition of Harrison's Principles in Internal Medicine. The data and concept for Figure 456-16 have been graciously provided by Dr. Miriam Udler and Dr. Jose Florez, Massachusetts General Hospital and Harvard Medical School, Boston.

457 The Practice of Genetics in Clinical Medicine

Susan M. Domchek, J. Larry Jameson, Susan Miesfeldt

APPLICATIONS OF MOLECULAR GENETICS IN CLINICAL MEDICINE

Genetic testing for inherited abnormalities associated with disease risk is increasingly used in the practice of clinical medicine. Germline alterations include chromosomal abnormalities specific gene mutations with autosomal dominant or recessive patterns of transmission **(Chap. 456)**, and single nucleotide polymorphisms (SNPs) with small relative risks associated with disease. Germline alterations are responsible for disorders beyond classic Mendelian conditions with genetic susceptibility to common adult-onset diseases such as asthma, hypertension, diabetes mellitus, macular degeneration, and a number of types of cancer. For many of these diseases, there is a complex interplay of genes (often multiple) and environmental factors that effect lifetime risk, age of onset, disease severity, and treatment options.

The expansion of human genetic knowledge is changing our understanding of pathophysiology and influencing our classification of diseases. Awareness of genetic etiology can have an impact on clinical management, including prevention and screening for or treatment of a range of diseases. Primary care physicians are relied upon to help patients navigate testing and treatment options. Consequently, they must understand the genetic basis for a large number of genetically influenced diseases, incorporate personal and family history to determine the risk for a specific mutation, and be positioned to provide counseling. Even if patients are seen by genetic specialists who assess

genetic risk and coordinate testing, primary care providers should offer information to their patients regarding the indications, limitations, risks, and benefits of genetic counseling and testing. They must also be prepared to offer risk-based management following genetic risk assessment. Given the pace of genetics, this is an increasingly difficult task. The field of clinical genetics has rapidly transitioned from single gene testing to multigene panel testing, with techniques such as whole-exome and genome sequencing on the horizon, increasing the complexity of test selection and interpretation, as well as patient education and medical decision-making.

COMMON ADULT-ONSET GENETIC DISORDERS

INHERITANCE PATTERNS

Adult-onset hereditary diseases follow multiple patterns of inheritance. Some are autosomal dominant conditions. These include many common cancer susceptibility syndromes such as hereditary breast and ovarian cancer (due to germline *BRCA1* and *BRCA2* mutations) and Lynch syndrome (caused by germline mutations in the mismatch repair genes *MLH1*, *MSH2*, *MSH6*, and *PMS2*). In both of these examples, inherited mutations are associated with a high penetrance (lifetime risk) of cancer, although penetrance is incomplete (risk is not 100%). In other conditions, although there is autosomal dominant transmission, penetrance is lower, thereby making the disorders more difficult to recognize. For example, germline mutations in *CHEK2* increase the risk of breast cancer, but with a moderate lifetime risk in the range of 20–30%, as opposed to 50–70% for mutations in *BRCA1* or *BRCA2*. Other adult-onset hereditary diseases are transmitted in an autosomal recessive fashion where two mutant alleles are necessary to cause full expression of disease. Examples include hemochromatosis and *MUTYH*-associated polyposis. There are more pediatric-onset autosomal recessive disorders, such as lysosomal storage diseases and cystic fibrosis.

The genetic risk for many adult-onset disorders is multifactorial. Risk can be conferred by genetic factors at a number of loci (polygenic), which individually have very small effects (usually with relative risks of <1.5). These risk loci (generally SNPs) combine with other genes and environmental factors in ways that are not well understood. Despite our incomplete understanding of gene-environment interactions, recent data suggest that a healthy lifestyle can mitigate risk associated with elevated polygenic risk for cardiovascular disease. SNP panels are available to assess risk of disease, but the optimal way of using this information in the clinical setting to improve patient outcomes remains uncertain.

Many diseases have multiple patterns of inheritance, adding to the complexity of evaluating patients and families for these conditions. For example, colon cancer can be associated with a single germline mutation in a mismatch repair gene (Lynch syndrome; autosomal dominant), biallelic mutations in *MUTYH* (autosomal recessive), or multiple SNPs (polygenic). Many more individuals will have SNP risk alleles than germline mutations in high-penetrance genes, but cumulative lifetime risk of colon cancer related to the former is modest, whereas the risk related to the latter is significant. Personal and family histories provide important insights into the possible mode of inheritance.

FAMILY HISTORY

When two or more first-degree relatives are affected with asthma, cardiovascular disease, type 2 diabetes, breast cancer, colon cancer, or melanoma, the relative risk for disease among close relatives ranges from two- to fivefold, underscoring the importance of family history for these prevalent disorders. In most situations, the key to assessing the inherited risk for common adult-onset diseases is the collection and interpretation of a detailed personal and family medical history in conjunction with a directed physical examination.

Family history should be recorded in the form of a pedigree, conveying health-related data on first- and second-degree relatives. When such pedigrees suggest inherited disease, they should be expanded to include additional family members. The determination of risk for an asymptomatic individual will vary depending on the size of the family, the number of unaffected relatives, the types of diagnoses, and the ages of disease onset. For example, a woman with two first-degree relatives with breast cancer is at greater risk for a specific Mendelian disorder if she has a total of 3 female first-degree relatives (with only 1 unaffected) than if she has a total of 10 female first-degree relatives (with 8 unaffected). Factors such as adoption and limited family structure (few women in a family or multiple early deaths unrelated to the target disease) should to be taken into consideration in the interpretation of a pedigree. Additional considerations include young age of disease onset (e.g., a 30-year nonsmoking woman with a myocardial infarction), unusual diseases (e.g., male breast cancer or medullary thyroid cancer), and the finding of multiple potentially related diseases in an individual (e.g., a woman with a history of both colon and endometrial cancer). Some adult-onset diseases are more prevalent in certain ethnic groups. For instance, 2.5% of individuals of Ashkenazi Jewish ancestry carry one of three founder mutation in *BRCA1* and *BRCA2*. Factor V Leiden mutations are much more common in Caucasians than in Africans or Asians.

Additional variables that should be documented are nonhereditary risk factors among those with disease (such as cigarette smoking and myocardial infarction; asbestos exposure and lung disease; and mantle radiation and breast cancer). Significant associated environmental exposures or lifestyle factors decrease the likelihood of a specific genetic disorder. In contrast, the absence of nonhereditary risk factors typically associated with a disease raises concern about a genetic association. A personal or family history of deep-vein thrombosis in the absence of known environmental or medical risk factors suggests a hereditary thrombotic disorder. The physical examination may also provide important clues about the risk for a specific inherited disorder. A patient presenting with xanthomas at a young age should prompt consideration of familial hypercholesterolemia. The presence of trichilemmomas in a woman with breast cancer raises concern for Cowden syndrome, associated with *PTEN* mutations.

Recall of family history is often inaccurate. This is especially so when the history is remote and families lose contact or separate geographically. It can be helpful to ask patients to fill out family history forms before or after their visits, because this provides them with an opportunity to contact relatives. Ideally, this information should be embedded in electronic health records and updated intermittently. Attempts should be made to confirm the illnesses reported in the family history before making important and, in certain circumstances, irreversible management decisions. This process is often labor intensive and ideally involves interviews of additional family members or review of medical records (including pathology reports), and death certificates.

Although many inherited disorders will be suggested by the clustering of relatives with the same or related conditions, it is important to note that disease penetrance is incomplete for most genetic disorders. As a result, the pedigree obtained in such families may not exhibit a clear Mendelian inheritance pattern because not all family members carrying the disease-associated alleles will manifest clinical evidence of the condition. Furthermore, genes associated with some of these disorders often exhibit variable disease expression. For example, the breast cancer–associated gene *BRCA2* can predispose to several different malignancies in the same family, including cancers of the breast, ovary, pancreas, skin (melanoma), and prostate. For common diseases such as breast cancer, some family members without the susceptibility allele (or genotype) may develop breast cancer (or phenotype) sporadically. Such *phenocopies* represent another confounding variable in the pedigree analysis.

Some of the aforementioned features of the family history are illustrated in **Fig. 457-1**. In this example, the proband (the individual serving as the starting point for genetic assessment in a family), a 36-year-old woman (IV-1), has a strong history of breast and ovarian cancer on the paternal side of her family. The early age of onset and the co-occurrence of breast and ovarian cancer in this family suggest the possibility of an inherited mutation in *BRCA1* or *BRCA2*, associated with the hereditary breast and ovarian cancer syndrome. It is unclear however, without genetic testing, whether her father harbors such a mutation and transmitted it to her. After appropriate genetic counseling of the proband

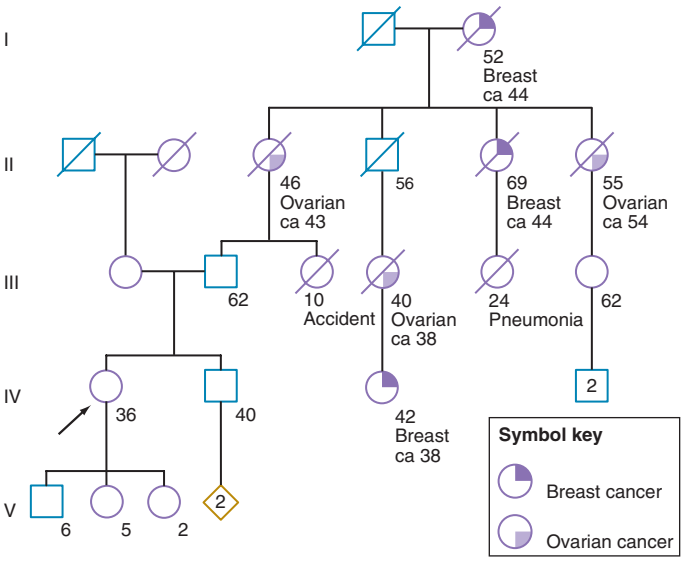

FIGURE 457-1 36-year-old woman (*arrow*) seeks consultation because of her family history of cancer. The patient expresses concern that the multiple cancers in her relatives imply an inherited predisposition to develop cancer. The family history is recorded, and records of the patient's relatives confirm the reported diagnoses.

and her family, the most informative and cost-effective approach to DNA analysis in this family is to test the cancer-affected 42-year-old living cousin for the presence of a *BRCA1* or *BRCA2* mutation. If a mutation is found, then it is possible to test for this particular alteration in other family members, if they so desire. In the example shown, if the proband's cousin has a *BRCA1* mutation, testing for this alteration (single site testing) would be offered to the proband's father. If he tests positive, there is a 50:50 probability that the mutation was transmitted to her, and genetic testing can be used to establish the absence or presence of this alteration. In contrast, if he tests negative for the known familial *BRCA1* mutation (a true negative result), the proband and her brother are not at risk for having inherited this variant.

GENETIC TESTING FOR ADULT-ONSET DISORDERS

A critical first step before initiating genetic testing is to ensure that the correct clinical diagnosis has been made, whether it is based on family history, characteristic physical findings, pathology, or biochemical testing. Such careful clinical assessment can define the phenotype. In the traditional model of genetic testing, testing is directed initially toward the most probable genes (determined by the phenotype), which prevents unnecessary testing. Many disorders exhibit the feature of locus heterogeneity, which refers to the fact that mutations in different genes can cause phenotypically similar disorders. For example, osteogenesis imperfecta **(Chap. 406)**, long QT syndrome **(Chap. 247)**, muscular dystrophy **(Chap. 441)**, and hereditary predisposition to breast **(Chap. 75)** or colon **(Chap. 77)** cancer can each be caused by mutations in a number of distinct genes. The patterns of disease transmission, disease risk, clinical course, and treatment may differ significantly depending on the specific gene affected. Historically, the choice of which gene to test has been determined by unique clinical and family history features and the relative prevalence of candidate genetic disorders. However, rapid changes in genetic testing techniques, as discussed below, are impacting this paradigm. It is now technically and financially feasible to sequence many genes (or even the whole exome) at one time. The incorporation of expanded testing for germline mutations is rapidly evolving both within the clinic as well as through direct-to-consumer marketing of genetic and genomic tests.

METHODOLOGIC APPROACHES TO GENETIC TESTING

Genetic testing is regulated and performed in much the same way as other specialized laboratory tests. In the United States, genetic testing laboratories are Clinical Laboratory Improvement Amendments (CLIA) approved to ensure that they meet quality and proficiency standards. A useful information source for various genetic tests is *www.genetests.org*. It should be noted that many tests need to be ordered through specialized laboratories.

Genetic testing is performed largely by DNA sequence analysis for mutations, although genotype can also be deduced through the study of RNA or protein (e.g., apolipoprotein E, hemoglobin S, and immunohistochemistry). For example, universal Lynch syndrome screening of colorectal and uterine cancers via immunohistochemical analysis for absence of expression of mismatch repair proteins is recommended by the National Comprehensive Cancer Center Network. The determination of DNA sequence alterations relies heavily on the use of polymerase chain reaction (PCR), which allows rapid amplification and analysis of the gene of interest. In addition, PCR enables genetic testing on minimal amounts of DNA extracted from a wide range of tissue sources including leukocytes, mucosal epithelial cells (obtained via saliva or buccal swabs), and archival tissues. Amplified DNA can be analyzed directly by DNA sequencing, or it can be hybridized to DNA chips or blots to detect the presence of normal and altered DNA sequences. Direct DNA sequencing is frequently used for determination of hereditary disease susceptibility and prenatal diagnosis. Analyses of large alterations (e.g., deletions, duplications, rearrangements, translocations) of the genome are possible using cytogenetics, fluorescent in situ hybridization (FISH), Southern blotting, or multiplex ligation-dependent probe amplification (MLPA).

Massively parallel sequencing (also called *next-generation sequencing*) has significantly altered the approach to genetic testing for adult-onset hereditary susceptibility disorder. This technology encompasses high-throughput approaches to DNA analysis which can reliably examine many genes at one time. Technically, this involves sequencing of millions of small fragments of DNA in parallel. Through bioinformatics, these fragments are pieced together by mapping the individual sequence reads to the human reference genome, a very different process than traditional Sanger sequencing which is time-consuming and expensive.

Multiplex panels for inherited susceptibility are commercially available and include testing of a number of genes that have been associated with the condition of interest. For example, panels are available for Brugada syndrome, hypertrophic cardiomyopathy, and Charcot-Marie-Tooth neuropathy. For many syndromes, this type of panel testing may make sense. However, in other situations, the clinical utility of panel testing is evolving and may be dependent on the particular composition of the panel. Currently available breast cancer susceptibility panels contain close to 30 genes with larger multi-cancer panels available. Some of the genes included in the larger multi-cancer panels have no known association with breast cancer or have only a modest associated risk and the clinical utility is uncertain. An additional problem of sequencing many genes, rather than focusing on leading candidate genes, is the identification of one or more variants of uncertain significance, discussed below, or an unexpected, yet clinically relevant result.

Whole-exome sequencing (WES) is also now commercially available, although largely used in individuals with syndromes unexplained by traditional genetic testing. As cost declines, WES may be more widely used. Whole-genome sequencing is also commercially available. Although it may be quite feasible to sequence the entire genome, there are many issues in doing so, including the daunting task of analyzing the vast amount of data generated. Other issues include: (1) the optimal way in which to obtain informed consent, (2) interpretation of frequent sequence variation of uncertain significance, (3) interpretation of alterations in genes with unclear relevance to specific human pathology, and (4) management of unexpected but clinically significant genetic findings.

Testing strategies are evolving as a result of these new genetic testing platforms. As the costs of multiplex gene panels and WES continue to fall, and as interpretation and understanding of the clinical relevance of such test results improve, there has been a shift to more extensive panel-based genetic testing in the clinic. For example, in the past, a 30-year-old woman with breast cancer but no family

history of cancer and no syndromic features would undergo *BRCA1/2* testing and would be offered *TP53* testing in light of her early onset disease (notably, a reasonable number of individuals offered *TP53* testing for Li-Fraumeni syndrome in the past declined because mutations are associated with extremely high cancer risks—including childhood cancers—in multiple organs and means to mitigate risk are uncertain).Without features consistent with other high-risk, breast cancer-related conditions like Cowden syndrome, the woman would not have been routinely offered *PTEN* analysis (associated with Cowden syndrome) or testing for other breast cancer-associated genes including *CHEK2* and *ATM*. It is now possible to synchronously analyze all of the aforementioned genes, along with genes such as BRIP and RAD51D (which are associated with moderate ovarian cancer risk but unclear risk for other cancers, including breast cancer) for a nominally higher cost than *BRCA1/2* testing alone. Concerns about such panels include appropriate consent strategies related to unclear findings, including one or more variants of uncertain significance, unanticipated results, and the uncertain clinical utility of some of the genes included on the panel **(Fig. 457-2)**.

Limitations to the accuracy and interpretation of genetic testing exist. In addition to technical errors, genetics tests are sometimes designed to detect only the most common mutations. In addition, genetic testing has evolved over time. For example, it was not possible to obtain commercially available comprehensive large genomic rearrangement testing for *BRCA1* and *BRCA2* until 2006. Therefore, a negative result must be qualified by the possibility that the individual may have a variant that was not detectable in the test. In addition, the individual may have a mutation in another untested cancer-associated gene or in a gene not yet reported to be associated with elevated disease risk. As such, unless there is known baseline mutation in the family, a negative result in an individual with a suggestive personal or family history is typically classified as an uninformative negative. In this circumstance, medical management decisions should be based on personal and family history. For example, a woman with a strong family history of breast cancer who receives an uninformative negative panel-based genetic test result may still be eligible for high-risk care, including consideration of MRI-based breast cancer screening in addition to close clinical surveillance and mammograms.

The finding of a VUS is another limitation to genetic testing. A VUS (also termed *unclassified variant*) is a sequence variation in a gene where the effect of the alteration on the function of the protein is not known. Many of these variants are single nucleotide substitutions (also called missense mutations) that result in a single amino acid change. Although many VUSs will ultimately be reclassified as benign variants, some will prove to be functionally important. As more genes are sequenced (for example, in a multiplex panel or through WES), the percentage of individuals found to have one or more VUSs increases significantly. The finding of a VUS is difficult for patients and providers alike and complicates decisions regarding medical management. In this setting, until there is further reclassification of the variant, ongoing screening, surveillance and care is typically determined based on personal and family history.

Clinical utility is an important consideration because genetic testing for susceptibility to chronic diseases is increasingly integrated into the practice of medicine. In some situations, there is proven clinical utility to genetic testing with significant evidence-based changes in medical management options and recommendations based on results. For example, there is clear evidence that risk-reducing bilateral salpingo-oophorectomy benefits women with a documented *BRCA1/2* mutation, relative to both ovarian and breast cancer-related risk. However, in many cases, the discovery of disease-associated genes has outpaced studies that assess how such information should be used in the clinical management of the patient and family. This is particularly true for moderate- and low-penetrance gene mutations. Therefore, predictive genetic testing should be approached with caution and offered to individuals who have been adequately counseled and have provided informed consent.

Predictive genetic testing falls into two distinct categories. Presymptomatic testing applies to diseases where a specific genetic alteration is associated with a near 100% likelihood of developing disease. In contrast, predisposition testing predicts a risk for disease that is <100%. For example, presymptomatic testing is available for those at risk for Huntington's disease; whereas, predisposition testing is considered for those at risk for hereditary colon cancer. It is important to note that for the majority of adult-onset disorders, testing is only predictive. Test results cannot reveal with confidence whether, when, or how the disease will manifest itself. For example, not everyone with the apolipoprotein ε4 allele will develop Alzheimer's disease, and individuals without this genetic marker can still develop the disorder.

The optimal testing strategy for a family is to initiate testing in a [target] disease-affected family member first. Identification of a mutation can direct the testing of other at-risk family members (whether symptomatic or not). In the absence of additional familial or environmental risk factors, individuals who test negative for the mutation found in the affected family member can be informed that they are at general population risk for that particular disease. Furthermore, they can be reassured that they are not at risk for passing the mutation on to their children. On the other hand, asymptomatic family members who test positive for the known mutation must be informed that they are at increased risk for disease development and for transmitting the alteration to their children.

Pretest counseling and education are important, as is an assessment of the patient's ability to understand and cope with test results. Genetic testing has implications for entire families, and thus individuals interested in pursuing genetic testing must consider how test results might

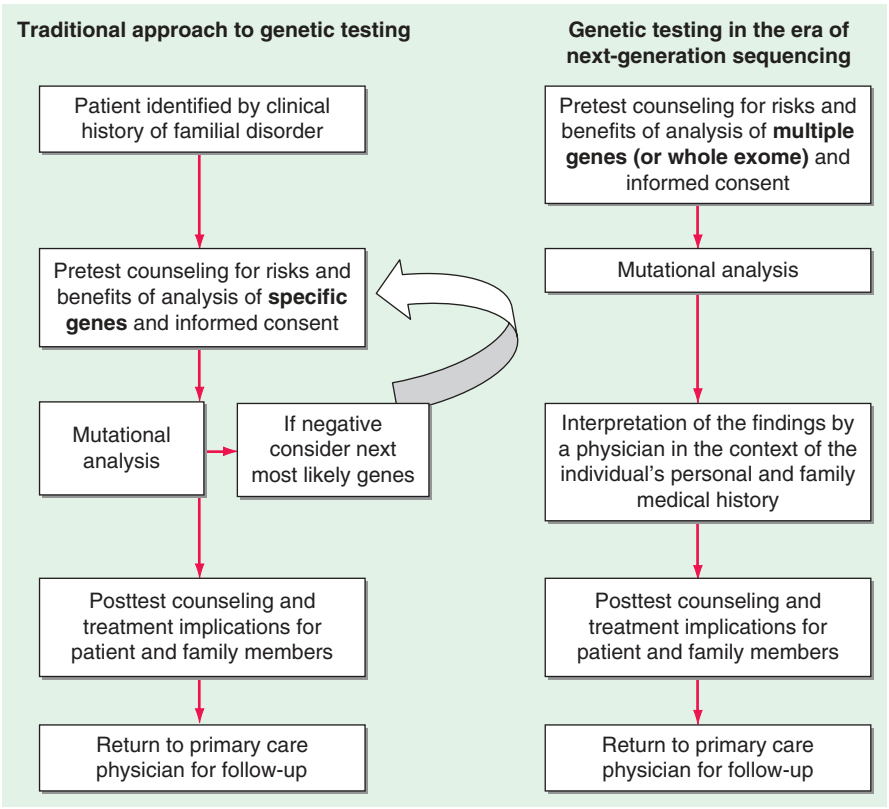

FIGURE 457-2 Approach to genetic testing.

impact their relationships with relatives, partners, spouses, and children. In families with a known genetic mutation, those who test positive must consider the impact of their carrier status on their present and future lifestyles; those who test negative may manifest survivor guilt. Parents who are found to have a disease-associated mutation often express considerable anxiety and despair as they address the issue of risk to their children. In addition, some individuals consider options such as preimplantation genetic diagnosis (PGD) in their reproductive decision-making.

When a condition does not manifest until adulthood, clinicians and parents are faced with the question of whether at-risk children should be offered genetic testing and, if so, at what age. Although the matter is debated, several professional organizations have cautioned that genetic testing for adult-onset disorders should not be offered to children. Many of these conditions have no known interventions in childhood to prevent disease; consequently, such information can pose significant psychosocial risk to the child. In addition, there is concern that testing during childhood violates a child's right to make an informed decision regarding testing upon reaching adulthood. On the other hand, testing should be offered in childhood for disorders that may manifest early in life, especially when management options are available. For example, children with multiple endocrine neoplasia 2 (MEN 2) may develop medullary thyroid cancer early in life and should be considered for prophylactic thyroidectomy **(Chap. 381)**. Similarly, children with familial adenomatous polyposis (FAP) due to a mutation in *APC* may develop polyps in their teens with progression to invasive cancer in the twenties, and therefore, colonoscopy screening is started between the ages of 10 and 15 years **(Chap. 77)**.

INFORMED CONSENT

Informed consent for genetic testing begins with education and counseling. The patient should understand the risks, benefits, and limitations of genetic testing, as well as the potential implications of test results. Informed consent should include a written document, drafted clearly and concisely in a language and format that is understandable to the patient. Because molecular genetic testing of an asymptomatic individual often allows prediction of future risk, the patient should understand all potential long-term medical, psychological, and social implications of testing. There have long been concerns about the potential for genetic discrimination. The Genetic Information Nondiscrimination Act (GINA) was passed in 2008 and provides some protections related to job and health insurance discrimination. It is important to explore with patients the potential impact of genetic test results on future health as well as disability and life insurance coverage. Patients should understand that alternatives remain available if they decide not to pursue genetic testing, including the option of delaying testing to a later date. The option of DNA banking should be presented so that samples are readily available for future use by family members, if needed.

FOLLOW-UP CARE AFTER TESTING

Depending on the nature of the genetic disorder, posttest interventions may include: (1) cautious surveillance and awareness; (2) specific medical interventions such as enhanced screening, chemoprevention, or risk-reducing surgery; (3) risk avoidance; and (4) referral to support services. For example, patients with known deleterious mutations in *BRCA1* or *BRCA2* are strongly encouraged to undergo risk-reducing salpingo-oophorectomy and are offered intensive breast cancer screening as well as the option of risk-reducing mastectomy. In addition, such women may wish to take chemoprevention with tamoxifen, raloxifene, or exemestane. Those with more limited medical management and prevention options, such as patients with Huntington's disease, should be offered continued follow-up and supportive services, including physical and occupational therapy and social services or support groups as indicated. Specific interventions will change as research continues to enhance our understanding of the medical management of these genetic conditions and more is learned about the functions of the gene products involved.

Individuals who test negative for a mutation in a disease-associated gene identified in an affected family member must be reminded that they may still be at risk for the disease. This is of particular importance for common diseases such as diabetes mellitus, cancer, and coronary artery disease. For example, a woman who finds that she does not carry the disease-associated mutation in *BRCA1* previously discovered in the family should be reminded that she still requires the same breast cancer screening recommended for the general population.

TABLE 457-1 Indications for Genetic Counseling

Advanced maternal age (>35 years)
Consanguinity
Previous history of a child with birth defects or a genetic disorder
Personal or family history suggestive of a genetic disorder
High-risk ethnic groups
Documented genetic alteration in a family member
Ultrasound or prenatal testing suggesting a genetic disorder

GENETIC COUNSELING AND EDUCATION

Genetic counseling is the process of helping people understand and adapt to the medical, psychological and familial implications of genetic contributions to disease. This process integrates the following: interpretation of family and medical histories to assess the chance of disease occurrence or recurrence; education about the natural history of the condition, inheritance pattern, testing, management, prevention, support resources and research; counseling to promote informed choices in view of risk assessment, family goals, ethical and religious values. Genetic counseling should be distinguished from genetic testing and risk-based medical screening and care, though genetic counselors are involved in these later issues.

Genetic risk assessment is complex and often involves elements of uncertainty. Genetic counseling can be useful in a wide range of situations **(Table 457-1)**. The role of the genetic counselor includes the following:

1. Gather and document a detailed family history.
2. Educate patients about general genetic principles related to disease risk, both for themselves and for others in the family.
3. Assess and enhance the patient's ability to cope with the genetic information offered.
4. Discuss how nongenetic factors may relate to the ultimate expression of disease.
5. Address medical management issues.
6. Assist in determining the role of genetic testing for the individual and the family.
7. Ensure the patient is aware of the indications, process, risks, benefits, and limitations of the various genetic testing options.
8. Assist the patient, family, and referring physician in the interpretation of the test results.
9. Ensure that the patient has the resources necessary to alert relatives to their risk, particularly in the face of a positive genetic test result.
10. Address the reproductive implications of a positive genetic test result, including the risk for a recessive disorder as well as discussion of reproductive options, including gamete donation or PGD.
11. Refer the patient and other at-risk family members for additional medical and support services, if necessary.

The principles of voluntary and informed decision-making, and protection of the individual's privacy and confidentiality are core principles in the practice of genetic counseling. Genetic counseling is generally offered in a *nondirective, noncoercive* manner, wherein patients learn to understand how their values factor into a particular medical decision. Nondirective counseling is particularly appropriate when there are no data demonstrating a clear benefit associated with a particular intervention or when an intervention is considered experimental. For example, nondirective genetic counseling is used when a person is deciding whether to undergo genetic testing for Huntington's disease. At this time, there is no clear benefit (in terms of medical outcome) to an at-risk individual undergoing genetic testing for this disease because its course cannot be altered by therapeutic interventions.

However, testing can have an important impact on the individual's perception of advanced care planning and his or her interpersonal relationships and plans for childbearing. Therefore, the decision to pursue testing rests on the individual's belief system and values. On the other hand, a more directive approach is appropriate when a condition can be treated. In a family with FAP, colon cancer screening and prophylactic colectomy should be recommended for known *APC* mutation carriers. The counselor and clinician following this family must ensure that the at-risk family members have access to the resources necessary to adhere to these recommendations.

Genetic education is central to an individual's ability to make an informed decision regarding testing options and treatment. An adequate knowledge of patterns of inheritance will allow patients to understand the probability of disease risk for themselves and other family members. It is also important to impart the concepts of disease penetrance and expression. For most complex adult-onset genetic disorders, asymptomatic patients should be advised that a positive test result does not always translate into future disease development. In addition, the role of nongenetic factors, such as environmental exposures and lifestyle, must be discussed in the context of multifactorial disease risk and disease prevention. Finally, patients should understand the natural history of the disease as well as the potential options for intervention, including screening, prevention, and in certain circumstances, pharmacologic treatment or prophylactic surgery.

THERAPEUTIC INTERVENTIONS BASED ON GENETIC RISK FOR DISEASE

Specific treatments are available for a number of genetic disorders. Strategies for the development of therapeutic interventions have a long history in childhood metabolic diseases; however, these principles have been applied in the diagnosis and management of adult-onset diseases as well **(Table 457-2)**. Hereditary hemochromatosis is usually caused by mutations in *HFE* (although other genes have been less commonly associated) and manifests as a syndrome of iron overload, which can lead to liver disease, skin pigmentation, diabetes mellitus, arthropathy, impotence in males, and cardiac issues **(Chap. 407)**. When identified

TABLE 457-2 Examples of Genetic Testing and Possible Interventions

GENETIC DISORDER	INHERITANCE	GENES	INTERVENTIONS
Oncologic			
Lynch syndrome (HNPCC)	AD	*MLH1, MSH2, MSH6, PMS2*	Early endoscopic screening; risk-reducing surgery
Familial adenomatous polyposis	AD	*APC*	Early and frequent endoscopy; prophylactic colectomy
Hereditary breast and ovarian cancer	AD	*BRCA1, BRCA2*	Risk reducing salpingo-oophorectomy; intensified breast surveillance including breast MRI; risk-reducing mastectomy
Hereditary diffuse gastric cancer	AD	*CDH1*	Prophylactic gastrectomy; enhanced breast cancer surveillance
Hematologic			
Factor V Leiden	AD	*F5*	Avoidance of thrombogenic risk factors
Hemophilia A	XL	*F8*	Factor VIII replacement
Hemophilia B	XL	*F9*	Factor IX replacement
Glucose 6-phosphate dehydrogenase deficiency	XL	*G6PD*	Avoidance of oxidant drugs and certain foods
Cardiovascular			
Hypertrophic cardiomyopathy	AD	>10 genes including *MYBPC3, MYH7, TNNT2, TPM1*	Echocardiographic screening; pharmacologic intervention; myomectomy
Long QT syndrome	AD, AR	>10 genes including *KCNQ1, SCN5A, KCNE1, KCNE2*	Electrocardiographic screening; pharmacologic intervention; implantable cardiac defibrillator devices
Marfan's syndrome	AD	*FBN1*	Echocardiographic screening; prophylactic beta blockers; aortic valve replacement as indicated
Gastrointestinal			
Familial Mediterranean fever	AR	*MEFV*	Colchicine
Hemochromatosis	AR	*HFE*	Phlebotomy
Pulmonary			
α_1 Antitrypsin deficiency	AR	*SERPINA1*	Avoidance of smoking and occupational and environmental toxins
Cystic fibrosis	AR	*CFTR*	Chest physiotherapy; agents to promote airway secretion clearance; *CFTR* modulators (G551D mutations); lung transplantation
Endocrine			
Neurohypophyseal diabetes insipidus	AD	*AVP*	Replace vasopressin
Familial hypocalciuric hypercalcemia	AD	*CASR*	Avoidance of parathyroidectomy
Multiple endocrine neoplasia type 2	AD	*RET*	Prophylactic thyroidectomy; screening for pheochromocytoma and hyperparathyroidism
Renal			
Polycystic kidney disease	AD, AR	*PKD1, PKD2, PKHD1*	Prevention of hypertension; prevention of urinary tract infections; kidney transplantation
Nephrogenic diabetes insipidus	XL, AR	*AVPR2, AQP2*	Fluid replacement; thiazides with or without amiloride
Neurologic			
Malignant hyperthermia	AD	*RYR1, CACNA1S*	Avoidance of precipitating anesthetics
Hyperkalemic periodic paralysis	AD	*SCN4A*	Diet rich in calcium and low in potassium; thiazides or acetazolamide
Duchenne's and Becker's muscular dystrophy	XL	*DMD*	Corticosteroids; physical therapy
Wilson's disease	AR	*ATP7B*	Zinc, trientene

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; HNPCC, hereditary nonpolyposis colorectal cancer; MRI, magnetic resonance imaging; XL, X-linked.

early, the disorder can be managed effectively with therapeutic phlebotomy. Therefore, when the diagnosis of hemochromatosis has been made in a proband, it is important to counsel other family members in order to minimize the impact of the disorder.

Preventative measures and therapeutic interventions are not restricted to metabolic disorders. Identification of familial forms of long QT syndrome, associated with ventricular arrhythmias, allows early electrocardiographic testing and the use of prophylactic antiarrhythmic therapy, overdrive pacemakers, or defibrillators. Individuals with familial hypertrophic cardiomyopathy can be screened by ultrasound, treated with beta blockers or other drugs, and counseled about the importance of avoiding strenuous exercise and dehydration. Those with Marfan's syndrome can be treated with beta blockers or angiotensin II receptor blockers and monitored for the development of aortic aneurysms.

The field of pharmacogenetics identifies genes that alter drug metabolism or confer susceptibility to toxic drug reactions. Pharmacogenetics seeks to individualize drug therapy in an attempt to improve treatment outcomes and reduce toxicity. Examples include thiopurine methyltransferase (TPMT) deficiency, dihydropyrimidine dehydrogenase deficiency, malignant hyperthermia, and glucose-6-phosphate deficiency. Despite successes in this area, it is not always clear how to incorporate pharmacogenetics into clinical care. For example, although there is an association with *CYP2C6* and *VKORC1* genotypes and warfarin dosing, there is no evidence that incorporating genotyping into clinical practice improves patient outcomes compared with clinical algorithms.

The identification of germline abnormalities that increase the risk of specific types of cancer is rapidly changing clinical management. Identifying family members with mutations that predispose to FAP or Lynch syndrome leads to recommendations of early cancer screening and prophylactic surgery, as well as consideration of chemoprevention and attention to healthy lifestyle habits. Similar principles apply to familial forms of melanoma as well as cancers of the breast, ovary, and thyroid. In addition to increased screening and prophylactic surgery, the identification of germline mutations associated with cancer may also lead to the development of targeted therapeutics, for example, the U.S. Food and Drug Administration (FDA) approval of the poly–ADP ribose polymerase (PARP) inhibitors olaparib and rucaparib for BRCA1/2-associated recurrent ovarian cancer.

Although the role of genetic testing in the clinical setting continues to evolve, such testing holds the promise of allowing early and more targeted interventions that can reduce morbidity and mortality. Rapid technologic advances are changing the ways in which genetic testing is performed. As genetic testing becomes less expensive and technically easier to perform, it is anticipated that there will be an expansion of its use. This will present challenges, but also opportunities. It is critical that physicians and other health care professionals keep current with advances in genetic medicine in order to facilitate appropriate referral for genetic counseling and judicious use of genetic testing, as well as to provide state-of-the-art, evidence-based care for affected or at-risk patients and their relatives.

458 Gene and Cell Based Therapy in Clinical Medicine

Katherine A. High, Malcolm K. Brenner

Gene transfer is a novel area of therapeutics in which the active agent is a nucleic acid sequence rather than a protein or small molecule. Because delivery of naked DNA or RNA to a cell is an inefficient process, most gene transfer is carried out using a vector, or gene delivery vehicle. These vehicles have generally been engineered from viruses by deleting some or all of the viral genome and replacing it with the therapeutic gene of interest under the control of a suitable promoter **(Table 458-1)**. Gene transfer strategies can thus be described in terms of three essential elements: (1) a vector; (2) a gene to be delivered, sometimes called the transgene; and (3) a physiologically relevant target cell to which the DNA or RNA is delivered. The series of steps in which the vector and donated DNA enter the target cell and express the transgene is referred to as *transduction*. Gene delivery can take place in vivo, in which the vector is directly injected into the patient, or, in the case of hematopoietic and some other target cells, ex vivo, with removal of the target cells from the patient, followed by return of the gene-modified autologous cells to the patient after manipulation in the laboratory. The latter approach effectively combines gene transfer techniques with cellular therapies **(Chap. 473)**.

Gene transfer is one of the most powerful concepts in modern molecular medicine and has the potential to address a host of diseases for which there are currently no available treatments. Clinical trials of gene therapy have been under way since 1990; the first gene therapy product to be licensed in the United States or Europe was licensed in 2012 (see below). Given that vector-mediated gene therapy is arguably one of the most complex therapeutics yet developed, consisting of both a nucleic acid and a protein component, this time course from first clinical trial to licensed product is noteworthy for being similar to those seen with other novel classes of therapeutics, i.e., monoclonal antibodies. Over 5000 subjects have been enrolled in gene transfer studies, and serious adverse events have been rare. Some of the initial trials were characterized by an overabundance of optimism and a failure to be appropriately critical of preclinical studies in animals; in addition, it was in some contexts not fully appreciated that animal studies are only a partial guide to safety profiles of products in humans (e.g., insertional mutagenesis, and human immune responses to the vector). Initial exuberance was driven by many factors, including an intense desire to develop therapies for hitherto untreatable diseases, lack of understanding of risks, and, in some cases, undisclosed financial conflicts of interest. After a teenager died of complications related to vector infusion, the field underwent a retrenchment; continued efforts led to a more nuanced understanding of the risks and benefits of these new therapies and more sophisticated selection of disease targets. Currently, gene therapies are being developed for a variety of disease entities **(Table 458-2)**.

GENE TRANSFER FOR GENETIC DISEASE

Gene transfer strategies for genetic disease generally involve gene addition therapy, an approach characterized by transfer of the missing gene to a physiologically relevant target cell. However, other strategies are possible, including supplying a gene that achieves a similar biologic effect through an alternative pathway (e.g., factor VIIa for hemophilia A); supplying an antisense oligonucleotide to splice out a mutant exon if the sequence is not critical to the function of the protein (as has been done with the dystrophin gene in Duchenne's muscular dystrophy); or downregulating a harmful effect through a small interfering RNA (siRNA). Two distinct strategies are used to achieve long-term gene expression: one is to transduce stem cells with an integrating vector, so that all progeny cells will carry the donated gene; and the other is to transduce long-lived cells, such as skeletal muscle or neurons. In the

TABLE 458-1 Characteristics of Gene Delivery Vehicles

Genome integration	Yes	Yes	Poor	Poor	Yes	No	No
Long-term expression	Yes	Yes	No	Yes	Yes	No	No
Main advantages	Persistent gene transfer in dividing cells	Persistent gene transfer in transduced tissues	Highly effective in transducing various tissues	Elicits few inflammatory responses, nonpathogenic	Persistent gene expression in both dividing and nondividing cells	Large packaging capacity with persistent gene transfer	Limited immune responses against the vector
Main disadvantages	Theoretical risk of insertional mutagenesis (occurred in multiple cases)	Might induce oncogenesis in some cases (not yet observed)	Viral capsid elicits strong immune responses	Limited packaging capacity	In need of a stable packaging system	Residual cytotoxicity with neuron specificity	Transduced gene expression is transient

Abbreviations: AAV, adeno-associated virus; HSV, herpes simplex virus.

case of long-lived cells, integration into the target cell genome is unnecessary. Instead, because the cells are nondividing, the donated DNA, if stabilized in an episomal form, will give rise to expression for the life of the cell. This approach thus avoids problems related to integration and insertional mutagenesis.

IMMUNODEFICIENCY DISORDERS: PROOF OF PRINCIPLE

Early attempts to effect gene replacement into hematopoietic stem cells (HSCs) were stymied by the relatively low transduction efficiency of retroviral vectors, which require dividing target cells for integration. Because HSCs are normally quiescent, they are a formidable transduction target. However, identification of cytokines that induced cell division without promoting differentiation of stem cells, along with technical improvements in the isolation and transduction of HSCs, led to modest but real gains in transduction efficiency.

The first convincing therapeutic effect from gene transfer occurred with X-linked severe combined immunodeficiency disease (SCID), which results from mutations in the gene (*IL2RG*) encoding the γc subunit of cytokine receptors required for normal development of T and natural killer (NK) cells **(Chap. 344)**. Affected infants present in the first few months of life with overwhelming infections and/or failure to thrive. In this disorder, it was recognized that the transduced cells, even if few in number, would have a proliferative advantage compared to the nontransduced cells, which lack receptors for the cytokines required for lymphocyte development and maturation. Complete reconstitution of the immune system, including documented responses to standard childhood vaccinations, clearing of infections, and remarkable gains in growth occurred in most of the treated children. However, among 20 children treated in the initial trials, five eventually developed a syndrome similar to T cell acute lymphocytic leukemia, with splenomegaly, rising white counts, and the emergence of a single clone of T cells. Molecular studies revealed that, in most of these children, the retroviral vector had integrated within a gene, *LMO-2* (LIM only-2), which encodes a component of a transcription factor complex involved in hematopoietic development. The retroviral long terminal repeat increases the expression of *LMO-2*, resulting in T cell leukemia.

The X-linked SCID studies were a watershed event in the evolution of gene therapy. They demonstrated conclusively that gene therapy could cure disease; of the 20 children treated in these initial trials, 18 achieved correction of the immunodeficiency disorder. Unfortunately, 5 of the 20 patients later developed a leukemia-like disorder, and one died of this complication; the rest are alive and free of complications at time periods ranging up to 17 years after initial treatment. These studies demonstrated that insertional mutagenesis leading to cancer was more than a theoretical possibility **(Table 458-3)**. As a result of the experience in these trials, all protocols using integrating vectors in hematopoietic cells must include a plan for monitoring sites of insertion and clonal proliferation. Strategies to overcome this complication have included using a "suicide" gene cassette in the vector, so that errant clones can be quickly ablated, or using "insulator" elements in the cassette, which can limit the activation of genes surrounding the insertion site. Lentiviral vectors, which can efficiently transduce nondividing target cells, are also likely to be safer than retroviral vectors, based on patterns of integration; the field is thus gradually moving toward these to replace retroviral vectors.

More clear-cut success has been achieved in a gene therapy trial for another form of SCID, adenosine deaminase (ADA) deficiency **(Chap. 344)**. ADA-SCID is clinically similar to X-linked SCID, although it can be treated by enzyme replacement therapy with a pegylated form

TABLE 458-2 Most Common Indications in Gene Therapy Trials

INDICATION	NUMBER
Cancer	1554
Monogenic diseases	248
Infectious diseases	180

TABLE 458-3 Potential Complications of Gene Therapy

Gene silencing—repression of promoter
Genotoxicity—complications arising from insertional mutagenesis
Phenotoxicity—complications arising from overexpression or ectopic expression of the transgene
Immunotoxicity—harmful immune response to either the vector or transgene; or a harmful immune response of the vector (e.g. CAR T cells)
Risks of horizontal transmission—shedding of infectious vector into environment
Risks of vertical transmission—germline transmission of donated DNA

of the enzyme (PEG-ADA), which leads to immune reconstitution but not always to normal T cell counts. Enzyme replacement therapy is expensive (annual costs: $200,000–$300,000). The initial trials of gene therapy for ADA-SCID were unsuccessful, but modifications of this protocol to include the use of HSCs rather than T cells as the target for transduction; discontinuation of PEG-ADA at the time of vector infusion, so that the transduced cells have a proliferative advantage over the nontransduced; and the use of a mild conditioning regimen to facilitate engraftment of the transduced autologous cells have led to success without the complications seen in the X-linked SCID trials. There have been no complications in the 10 children treated on the Milan protocol, with a median follow-up of >11 years. This therapy was approved in 2016 by the European Medicines Agency. ADA-SCID, then, is an example where gene therapy has changed therapeutic options for patients. For those with a human leukocyte antigen (HLA)-identical sibling, bone marrow transplantation is still the best treatment option, but this includes only a minority of those affected. For those without an HLA-identical match, gene therapy has comparable efficacy to PEG-ADA, does not require repetitive injections, and does not present the risk of development of neutralizing antibodies to the bovine enzyme.

NEURODEGENERATIVE DISEASES: EXTENSION OF PRINCIPLE

The SCID trials gave support to the hypothesis that gene transfer into HSCs could be used to treat any disease for which allogeneic bone marrow transplantation was therapeutic. Moreover, the use of genetically modified autologous cells carried several advantages including no risk of graft-versus-host disease, guaranteed availability of a "donor" (unless the disease itself damages the stem cell population of the patient), and low likelihood of failure of engraftment. Cartier and Aubourg capitalized on this realization to conduct the first trial of lentiviral vector transduction of HSCs for a neurodegenerative disorder, X-linked adrenoleukodystrophy (ALD). X-linked ALD is a fatal demyelinating disease of the central nervous system caused by mutations in the gene encoding an adenosine triphosphate–binding cassette transporter. Deficiency of this protein leads to accumulation of very-long-chain fatty acids in oligodendrocytes and microglia, disrupting myelin maintenance by these cells. Affected boys present with clinical and neuroradiographic evidence of disease at age 6–8 and usually die before adolescence. Following lentiviral transduction of autologous HSCs in young boys with the disease, dramatic stabilization of disease occurred, demonstrating that stem cell transduction could work for neurodegenerative as well as immunologic disorders. Investigators in Milan carried this observation one step further to develop a treatment for another neurodegenerative disorder that has previously responded poorly to bone marrow transplantation. Metachromatic leukodystrophy is a lysosomal storage disorder caused by mutations in the gene encoding arylsulfatase A (ARSA). The late infantile form of the disease is characterized by progressive motor and cognitive impairment, and death within a few years of onset, due to accumulation of the ARSA substrate sulfatide in oligodendrocytes, microglia, and some neurons. Recognizing that endogenous levels of production of ARSA were too low to provide cross-correction by allogeneic transplant, Naldini and colleagues engineered a lentiviral vector that directed supraphysiologic levels of ARSA expression in transduced cells. Transduction of autologous HSCs from children born with the disease, at a point when they were still presymptomatic, led to preservation and continued acquisition of motor and cognitive milestones at time periods as long as 32 months after affected siblings had begun to lose milestones. These results illustrate that the ability to engineer levels of expression can allow gene therapy approaches to succeed where allogeneic bone marrow transplantation cannot. It is likely that a similar approach will be used in other neurodegenerative conditions.

Transduction of HSCs to treat the hemoglobinopathies is an obvious extension of studies already conducted but represents a higher hurdle in terms of the extent of transduction required to achieve a therapeutic effect. Trials are now under way for thalassemia and sickle cell disease, and for a number of other hematologic disorders, including Wiskott-Aldrich syndrome, and chronic granulomatous disease.

LONG-TERM EXPRESSION IN GENETIC DISEASE: IN VIVO GENE TRANSFER WITH RECOMBINANT ADENO-ASSOCIATED VIRAL VECTORS

Recombinant adeno-associated viral (AAV) vectors have emerged as attractive gene delivery vehicles for genetic disease. Engineered from a small replication-defective DNA virus, they are devoid of viral coding sequences and trigger very little immune response in experimental animals. They are capable of transducing nondividing target cells, and the donated DNA is stabilized primarily in an episomal form, thus minimizing risks arising from insertional mutagenesis. Because the vector has a tropism for certain long-lived cell types, such as skeletal muscle, the central nervous system (CNS), and hepatocytes, long-term expression can be achieved even in the absence of integration.

FIRST LICENSED PRODUCT

These features of AAV were used to develop the first licensed gene therapy product in Europe, an AAV vector for treatment of the autosomal recessive disorder lipoprotein lipase (LPL) deficiency. This rare disorder (1–2/million) is due to loss-of-function mutations in the gene encoding LPL, an enzyme normally produced in skeletal muscle and required for the catabolism of triglyceride-rich lipoproteins and chylomicrons. Affected individuals have lipemic serum and may have eruptive xanthomas, hepatosplenomegaly, and in some cases, recurrent bouts of acute pancreatitis. Clinical trials demonstrated the safety of intramuscular injection of AAV-LPL and its efficacy in reducing frequency of pancreatitis episodes in affected individuals, leading to drug approval in Europe. Additional clinical trials currently under way that use AAV vectors in the setting of genetic disease include those for muscular dystrophies, spinal muscular atrophy, Parkinson's disease, Batten's disease, ornithine transcarbamylase deficiency, hemophilia B and A, several forms of congenital blindness, and a variety of other inherited conditions.

HEMOPHILIA

Hemophilia **(Chap. 61)** has long been considered a promising disease model for gene transfer, because the gene product does not require precise regulation of expression and biologically active clotting factors can be synthesized in a variety of tissue types, permitting latitude in the choice of target tissue. Moreover, raising circulating factor levels from <1% (levels seen in those severely affected) into the range of 5% greatly improves the phenotype of the disease. Preclinical studies with recombinant AAV vectors infused into skeletal muscle or liver have resulted in long-term (>5 years) expression of factor VIII or factor IX in the hemophilic dog model. Administration to skeletal muscle of an AAV vector expressing factor IX in patients with hemophilia B was safe and resulted in long-term expression as measured on muscle biopsy, but circulating levels never rose to >1% for sustained periods, and a large number of IM injections (>80–100) was required to access a large muscle mass. Intravascular vector delivery has been used to access large areas of skeletal muscle in animal models of hemophilia and will likely be tested as a route of administration for muscular dystrophy disorders in upcoming trials.

The first trial of an AAV vector expressing factor IX delivered to the liver in humans with hemophilia B resulted in therapeutic circulating levels at the highest dose tested, but expression at these levels (>5%) lasted for only 6–10 weeks before declining to baseline (<1%). A memory T cell response to the viral capsid, present in humans but not in other animal species (which are not natural hosts for the virus), likely led to the loss of expression (Table 458-3). In response to these findings, a second trial included a short course of prednisolone, to be administered if factor IX levels began to decline. This approach resulted in long-term expression (>7 years, with observation ongoing) of factor IX, in the range of 2–7%, in men with severe hemophilia B. By using as the transgene a high specific activity variant of FIX, it has been possible to lower the vector dose required, reducing the risk of the immune response, and increasing the plateau levels of FIX into the range of 15–45%. Current efforts are focused on expanding these trials, and extending the approach to hemophilia A.

RETINAL GENE THERAPY

A logical conclusion from the early experience with AAV in liver in the hemophilia trial was that avoidance of immune responses was key to long-term expression. Thus immunoprivileged sites such as the retina began to attract substantial interest as therapeutic targets. This inference has been elegantly confirmed in the setting of the retinal degenerative disease Leber congenital amaurosis (LCA). Characterized by early-onset blindness, LCA was not previously treatable and is caused by mutations in several different genes; ~10% of cases of LCA are due to a mutation in a gene, *RPE65*, encoding a retinal pigment epithelial-associated 65-kDa protein. In dogs with a null mutation in *RPE65*, sight was restored after subretinal injection of an AAV vector expressing *RPE65*. Transgene expression appears to be stable, with the first animals treated >10 years ago continuing to manifest electroretinal and behavioral evidence of visual function. A Phase 3 trial, the first randomized controlled trial in human gene therapy, of an AAV vector encoding RPE65 was completed, and demonstrated improvement in multiple measures of retinal and visual function. This product has now been licensed by the U.S. Food and Drug Administration (FDA), and is the first licensed AAV gene therapy product in the United States. Trials for other inherited retinal degenerative disorders such as choroideremia are under way, as are studies for certain complex acquired disorders such as age-related macular degeneration, which affects several million people worldwide. The neovascularization that occurs in age-related macular degeneration can be inhibited by expression of vascular endothelial growth factor (VEGF) inhibitors such as angiostatin or through the use of RNA interference (RNAi)-mediated knockdown of VEGF. Early-phase trials of an AAV vector designed to achieve long-term inhibition of the biological effects of VEGF through a soluble VEGF receptor, however, failed to provide convincing evidence of efficacy, illustrating the challenges of developing genetic approaches for complex acquired disorders.

GENE THERAPY FOR CANCER

The majority of clinical gene transfer experience has been in subjects with cancer. The intent has been to increase the precision of cancer therapies and thereby make them less toxic and more effective. Most approaches have either modified the tumor directly, or altered the host's response to the malignancy to produce immune effector cells that are precisely targeted to the tumor phenotype.

MODIFYING THE CANCER

Since cancer is an (acquired) genetic disorder, initial efforts were directed at correcting the genetic deficits of the tumor or introducing lethal genes. Two major and persisting obstacles, however, are the poor biodistribution and transduction efficiency of all currently available vectors, and the heterogeneity and genetic instability of the tumor targets themselves, so that correction of single driver mutations does not preclude the evolution of a resistant population.

Tumor Correction One widely used direct intratumoral approach was adenoviral-mediated expression of the tumor suppressor p53, which is mutated in many different cancers. Initial studies showed some complete and partial responses in squamous cell carcinoma of the head and neck, esophageal cancer, and non-small cell lung cancer, but as yet there have been no successful product licensing studies for this approach except in China.

Pro-Drug Metabolizing Genes Efforts to overcome the above limitations have included the introduction of a prodrug or a suicide gene that would increase sensitivity of tumor cells to cytotoxic drugs. A frequently used strategy has been intratumoral injection of an adenoviral vector expressing the thymidine kinase (*TK*) gene. Cells that take up and express the *TK* gene can be killed after the administration of gancyclovir, which is phosphorylated to a toxic nucleoside by *TK*. The advantage of this approach is that the effects of transducing even a limited number of tumor cells are amplified by the spread of active drug to adjacent tumor cells. Although the approach continues to be examined in aggressive brain tumors and locally recurrent prostate, breast, and colon tumors, progress remains slow, and systemic benefits against metastatic disease have not been established.

MODIFYING THE HOST

Recruiting the Immune System The successful use of monoclonal antibodies that produce anti-tumor activity by activating the immune response has demonstrated the feasibility of manipulating the immune system to recognize the abnormal pattern of antigen expression on tumor cells. Immune cells are capable of almost unlimited expansion and persistence and can provide long-term tumor control. They can also traffic to tumor sites irrespective of location and, in principle, have the potential to evolve with the changing pattern of tumor cell phenotype and function.

Vaccination This strategy promotes more efficient recognition of tumor cells by the immune system, but the development of a therapeutic as opposed to the preventative vaccines required to combat infectious diseases has proved to be a considerable challenge. Approaches have included transduction of tumor cells with immune-enhancing genes encoding cytokines, chemokines, or co-stimulatory molecules, and the ex vivo manipulation of dendritic cells to enhance the presentation of tumor antigens. A dendritic cell vaccine for treatment of recurrent prostate cancer has received approval in the United States but its limited potency and high cost constrained commercial success.

Adoptive Cell Transfer Host immune cells such as T cells, NK cells, and others can be modified to express new transgenic receptors intended to recognize tumor cells and their microenvironment (Fig. 458-1). Retargeting may use a modification of the cells' own receptor or a synthetic chimeric antigen receptor (CAR) that is usually composed of the antigen recognition portion of an antibody and the signaling components of the cell's native antigen receptor. Both approaches have been successful, with significant responses reported with native receptors targeted to melanoma and synovial cell sarcoma and—most dramatically—with CARs targeted to CD19, an antigen expressed at high levels on normal and many malignant B cells. Infused CAR T cells can expand many thousand fold in vivo, persist long term, and have produced >90% complete response rates when targeting intractable B-acute lymphoblastic leukemia. Many responses are sustained long term and the approach has been licensed by the U.S. FDA. Broader application of adoptive T cell approaches is limited by: (1) The immune inhibitory microenvironment associated with most tumors; recent studies further modify the T cells with countermeasures to tumor inhibitory signals; (2) Acute and sometimes fatal systemic inflammatory and neurological toxicities during the phase of T-cell

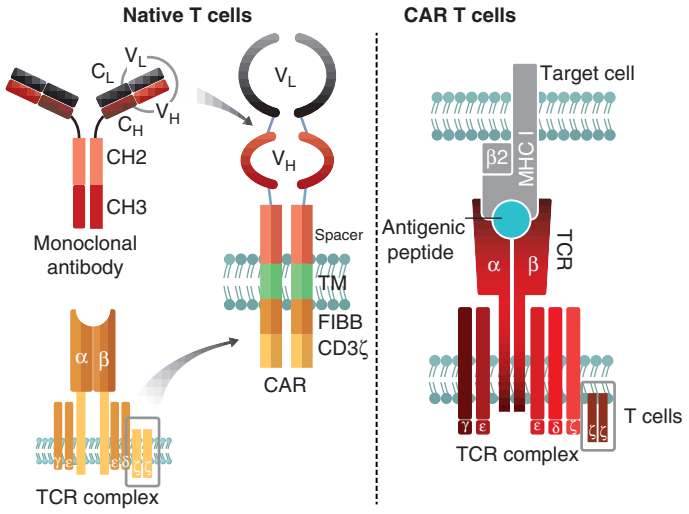

FIGURE 458-1 T cell receptors. A native T cell receptor (TCR) recognizes processed peptide antigens bound to major histocompatibility (MHC) molecules through its αβ chains. Signaling then occurs through a multichain intracellular CD3 complex. A chimeric antigen receptor (CAR) usually contains an extracellular receptor component derived from the antigen binding portion (V_H and V_L) of a monoclonal antibody. This produces a receptor that can recognize either protein or non-protein antigens independent of the MHC. A transmembrane (TM) domain then connects this receptor to the ζ chain of the CD3 complex derived from the native TCR.

expansion and tumor killing; (3) The off-target/or on-target but off-tumor effects that may damage normal host tissues (such as normal B cells following CD19 CAR therapy); (4) The cost, time, and complexity of manufacture; a particular problem when antigens unique to each tumor's individual mutations are targeted (neoantigens), rather than widely shared tumor associated antigens.

Non-Immunological Modifications to Host Gene transfer can be used to protect normal cells from the toxicities of chemotherapy and thereby increase the therapeutic index of these drugs. The most extensively studied approach has been to transduce hematopoietic cells with genes encoding resistance to chemotherapeutic agents, including the multidrug resistance gene *MDRI* or the gene encoding O^6-methylguanine DNA methyltransferase (*MGMT*). Although such approaches reduce hematologic toxicity, cytotoxic dose escalation quickly reveals dose-limiting toxicities to other organ systems.

Finally, gene transfer can be used to inhibit the host angiogenesis required for tumor support, for example by constitutive expression of inhibitors such as angiostatin and endostatin, or the transfer of T cells genetically modified to recognize antigens specific to newly forming vasculature. These studies are early-phase.

TABLE 458-4 Taking History from Subjects Enrolled in Gene Transfer Studies

Elements of History for Subjects Enrolled in Gene Transfer Trials
1. What vector was administered? Is it predominantly integrating (retroviral, lentiviral, herpesvirus [latency and reactivation]) or nonintegrating (plasmid, adenoviral, adeno-associated viral)?
2. What was the route of administration of the vector?
3. What was the target tissue?
4. What gene was transferred in? A disease-related gene? A marker?
5. Were there any adverse events noted after gene transfer?
Screening Questions for Long-Term Follow-Up in Gene Transfer Subjects[a]
1. Has a new malignancy been diagnosed?
2. Has a new neurologic/ophthalmologic disorder, or exacerbation of a preexisting disorder, been diagnosed?
3. Has a new autoimmune or rheumatologic disorder been diagnosed?
4. Has a new hematologic disorder been diagnosed?

[a]Factors influencing long-term risk include: integration of the vector into the genome, vector persistence without integration, and transgene-specific effects.

COMBINATION APPROACHES—MODIFICATION OF HOST AND TUMOR BY VIROTHERAPY

Immuno Oncolytic Viruses These viruses are genetically modified to replicate in malignant but not normal cells. The replicating vectors thus proliferate and spread within the tumor, facilitating eventual tumor clearance. However, physical limitations to viral spread, including fibrosis, intermixed normal cells, basement membranes, and necrotic areas within the tumor, may reduce clinical efficacy, and their activity against metastatic disease has proved limited. Recently, the FDA granted licensing approval to talimogene laherparepvec, an oncolytic herpes virus containing the human GM-CSF gene, for treatment of melanoma. This success has led to resurgent interest in combining the local tumor destruction and tumor antigen release mediated directly by oncolytic viruses with the recruitment of a systemic immune response mediated by immunostimulatory genes contained within the oncolytic virus. In principle such immune-oncolytic viruses should produce responses in both local and metastatic disease. Numerous novel viral agents are now entering early phase clinical testing.

OTHER APPROACHES

This chapter has focused on gene addition therapy, in which a normal gene is transferred to a target tissue to drive expression of a gene product with therapeutic effects. Another powerful technique under development is genome editing, in which a mutation is corrected in situ, generating a wild-type copy under the control of the endogenous regulatory signals. This approach makes use of novel reagents including zinc finger nucleases, TALENs and CRISPR, which introduce double-stranded breaks into the DNA near the site of the mutation and then rely on a donated repair sequence and cellular mechanisms for repair of double-strand breaks to reconstitute a functioning gene. These approaches have only recently entered the stage of clinical investigation. Another strategy recently introduced into clinical trials is the use of siRNAs or short hairpin RNAs as transgenes to knock down expression of deleterious genes (e.g., mutant huntingtin in Huntington's disease or genes of the hepatitis C genome in infected individuals).

SUMMARY

The power and versatility of gene transfer approaches are such that there are few serious disease entities for which gene transfer therapies are *not* under development. The development of new classes of therapeutics typically takes two to three decades; monoclonal antibodies and recombinant proteins are recent examples. Gene therapeutics, which entered clinical testing in the early 1990s, traversed the same time course. Examples of clinical success are now abundant, and gene therapy approaches are likely to become increasingly important as a therapeutic modality in the twenty-first century. A central question to be addressed is the long-term safety of gene transfer, and regulatory agencies have mandated a 15-year follow-up for subjects enrolled in gene therapy trials (Table 458-4). Realization of the therapeutic benefits of modern molecular medicine will depend on continued progress in gene transfer technology.

459 The Human Microbiome

Neeraj K. Surana, Dennis L. Kasper

"All disease begins in the gut."

–Hippocrates

Nearly two and a half millennia after Hippocrates made this statement, we are just coming to truly appreciate its profundity. Since the beginning of humankind, scholars have been investigating the underpinnings of disease with an almost singular focus on the human side of the equation. Microbes were not recognized as an important cause of disease until the inception of the "germ theory" in the late nineteenth century. During the first century of medical microbiology, research largely centered on the role of microbes as pathogens. Only recently has there been a resurgence of interest in understanding how commensal organisms—the bacteria, viruses, fungi, and Archaea that

make up the *microbiota*—impact human physiology. The idea that these microorganisms are vital to the well-being of humans has challenged our traditional notions of "self." Indeed, a human being can most accurately be described as a *holobiont*: a complex assemblage of human cells and microorganisms interacting in an elaborate *pas de deux* that drives normal physiologic processes.

Aimed at a better understanding of this relationship, myriad studies during the past decade have begun to catalogue the microbiota at various body sites and in a multitude of disease conditions. Diseases in virtually every organ system have been associated with changes in the microbiota. Indeed, the microbiota has been linked to intestinal disorders, disturbances in metabolic function, autoimmune diseases, and psychiatric conditions and has been shown to influence susceptibility to infection and the efficacy of pharmaceutical therapies. Knowledge of the specific mechanism(s) underlying most of these microbe–disease associations is lacking; it remains unclear whether the disease-associated alterations in the microbiota represent mere biomarkers of disease, a causal relationship, or a combination of the two. Although cause-and-effect relationships are still being elucidated for many diseases, it is clear that humans coexist in an intricate relationship with commensal organisms. This chapter explores in detail the nature of these host–commensal interactions, focusing on how this information might be translated into clinically meaningful interventions.

HISTORICAL PERSPECTIVE

Massive undertakings, such as the Human Microbiome Project (HMP) sponsored by the National Institutes of Health and MetaHIT sponsored by the European Commission, have catalogued all the bacteria present at multiple body sites in people with and without disease. Coupled with the confluence of advances in sequencing technologies **(Chap. 474)**, gnotobiotic animal availability, and microbial culture, significant progress has been made toward an understanding of the interplay between the microbiota and human health. However, recent findings were foreshadowed by work done centuries ago.

The human microbiota was first explored in 1683 when Antony van Leeuwenhoek described in a letter to the Royal Society of London the "very little living animalcules, very prettily a-moving" that he had observed in the plaque between his teeth. Leeuwenhoek went on to perform the first comparative "microbiota" studies by assessing how fecal and oral bacteria differ, how oral microbes change in the setting of disease (e.g., alcoholism and tobacco use), and how microbial composition changes across the age spectrum (e.g., in young children versus old men). He attempted—unsuccessfully—to eliminate these bacteria. Although Leeuwenhoek was not taken seriously when he first reported his findings, his studies laid the groundwork for what is now the field of microbiome research, and investigators are still trying to answer many of the same overarching questions that he raised more than three centuries ago.

Although Leeuwenhoek first reported the existence of bacteria and their association with humans at the end of the seventeenth century, the significance of commensal bacteria was not realized until late in the nineteenth century. In 1885, Pasteur suggested that animals could not survive if they were "artificially and completely deprived of the common microbes." Although Pasteur's preconceived ideas were proven incorrect in 1912 by the advent of germ-free animals (animals raised without exposure to any microorganisms), the underlying concept that commensal organisms are critical to health has held up. Élie Metchnikoff made another conceptual advance in this field by suggesting at the beginning of the twentieth century that clinical outcomes could be altered by the administration of specific beneficial organisms (*probiotics*). In particular, Metchnikoff believed that aging was caused by toxic bacteria in the gut and that lactic acid–producing bacteria (e.g., *Lactobacillus* species) present in sour milk and yogurt could mitigate against this process. The data behind this specific claim are still lacking, but recent discoveries offer continued hope that the microbiome can be effectively harnessed to protect against and treat a variety of diseases. Thus, although the field of microbiome research is sometimes considered to have emerged over the last one or two decades, the basic tenets—that the microbiota varies according to body site and clinical characteristics, that microbes are critical for human health, and that specific modulation of the microbiota may lead to improved clinical outcomes—are far from new.

A PRIMER ON TAXONOMY

Given that microbiome-based studies have identified and compared microbes at different levels of taxonomic resolution **(Fig. 459-1)**, some understanding of taxonomy is essential for better comprehension of the implications of these studies. Of the ~100 bacterial phyla that exist in nature, only five (Actinobacteria, Bacteroidetes, Firmicutes, Fusobacteria, and Proteobacteria) are dominant members of the human microbiome. Each of these phyla can be further categorized into multiple classes, orders, families, genera, and species. Early studies on the microbiota focused on changes in the relative abundance at the phylum level between different groups (e.g., obese versus normal-weight patients); however, these comparisons are at such a broad taxonomic level that they often provide little or no biological insight. As illustrated in Fig. 459-1, drawing comparisons between organisms in two different bacterial phyla is analogous to comparing humans to sea stars: the evolutionary distance between the two is tremendous. The limitations of current bioinformatic tools require lumping together of taxonomically related strains and thus cloud the richness of microbial ecology. Examining microbial profiles at the phylum, family, or even genus level—as is often done at present—ignores the great heterogeneity within different strains of the same bacterial species. The analytical pipelines are just now beginning to enable strain-level comparisons, and these improvements will likely facilitate our ongoing investigation of host–commensal interactions.

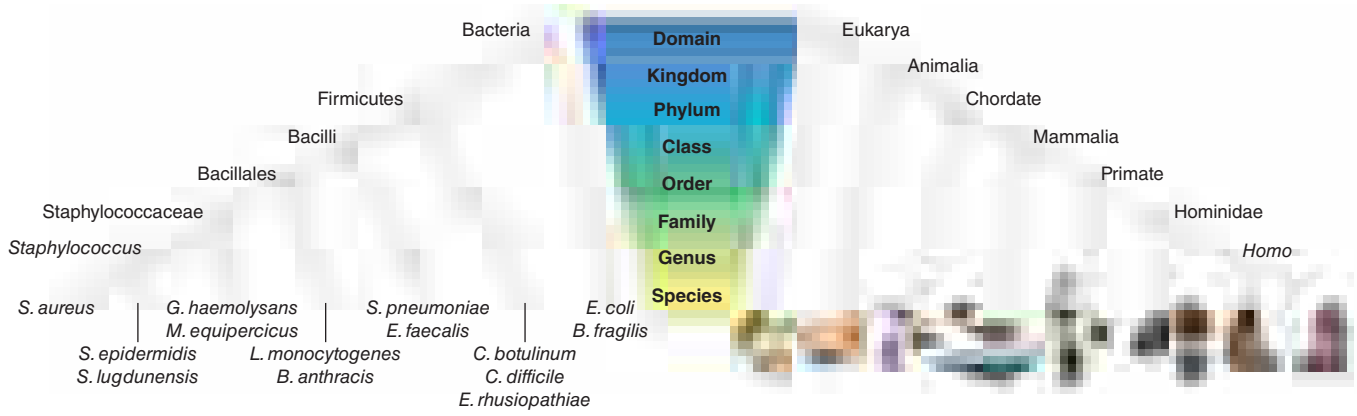

FIGURE 459-1 Juxtaposition of bacterial and human taxonomy highlights the evolutionary distance between different taxonomic levels. The listed species represent exemplars that are members of the taxon to which they are connected but that are not contained within the next-lower-level taxon listed. For example, *Clostridium botulinum*, *Clostridium difficile*, and *Erysipelothrix rhusiopathiae* are members of the phylum Firmicutes, but are in classes other than Bacilli. Similarly, starfish and humans are both members of the kingdom Animalia, but they are in different phyla.

THE MICROBIOTA AND HUMAN HEALTH

OVERVIEW OF THE HUMAN MICROBIOTA

The overwhelming majority of microbiota studies have focused on stool, given that this sample type represents the most ecologically rich anatomic site, is easy to obtain, and can readily be followed longitudinally in the same individual. A landmark study by the HMP sought to define the "normal" microbiota throughout the entire body in healthy Western adults. To this end, the microbial populations at 15–18 body sites were characterized in 242 people. One striking finding was that all samples from a given body region (e.g., skin) were more similar to each other than they were to samples from a different body region (e.g., stool), even in the same individual **(Fig. 459-2*A*)**. In essence, the effect of the anatomic site on microbial composition is far greater than the effect of heterogeneity between individuals. That said, there was a remarkable amount of inter-individual variation at any given body site **(Fig. 459-2*B*)**. In stool, for example, the abundance of the phylum Bacteroidetes ranged from ~10% in some individuals to >90% in others. Remarkably, even with person-to-person variability and differences among body sites, the functional capacity of the microbiota—assessed using metagenomic data to identify gene pathways—was quite similar across different people and different body sites **(Fig. 459-2*C*)**. This discrepancy between the substantial differences in microbial composition and the little or no resulting change in the functional properties of the microbiota reflects an important ecologic property of the microbiota: the microbial communities at different body sites and in different people assemble in such a way that all the core metabolic functions are maintained. This finding also hints at the likely possibility of significant functional redundancy within the microbiota, with different species executing the same biological functions at different anatomic sites.

While the HMP provided the first large-scale catalogue of the microbiome in multiple people and at many different body sites, the amount of data generated by what, at the time, was by far the largest microbiome study has been dwarfed by subsequent studies. These more recent studies have confirmed the HMP's major tenets: the composition of the microbiota differs by body site, there is tremendous inter-individual variation, and the microbial gene content is relatively conserved irrespective of the body site or individual. No microbial species are ubiquitous in all individuals and at all body sites, but some species are highly prevalent at a given body site: in the HMP study, *Staphylococcus epidermidis* was present in 93% of nares samples and *Escherichia coli* in 61% of stool samples. These findings highlight the remarkable personalization of the human microbiome. While the human genome is typically >99.5% identical in different people, the microbiotas of two individuals may not overlap at all. Although the "precision medicine" approach currently focuses on teasing out how differences in the human genome relate to different clinical end points, the human microbiome clearly represents a critical component for consideration.

THE MICROBIOTA BY THE NUMBERS

It has long been known that the human-associated microbiota is numerically dense. Leeuwenhoek estimated that there were more "animals living in the scrum on the teeth in man's mouth than there are men in a kingdom." Specific enumeration of the components of the microbiota has been challenging, in part because of its variability across time,

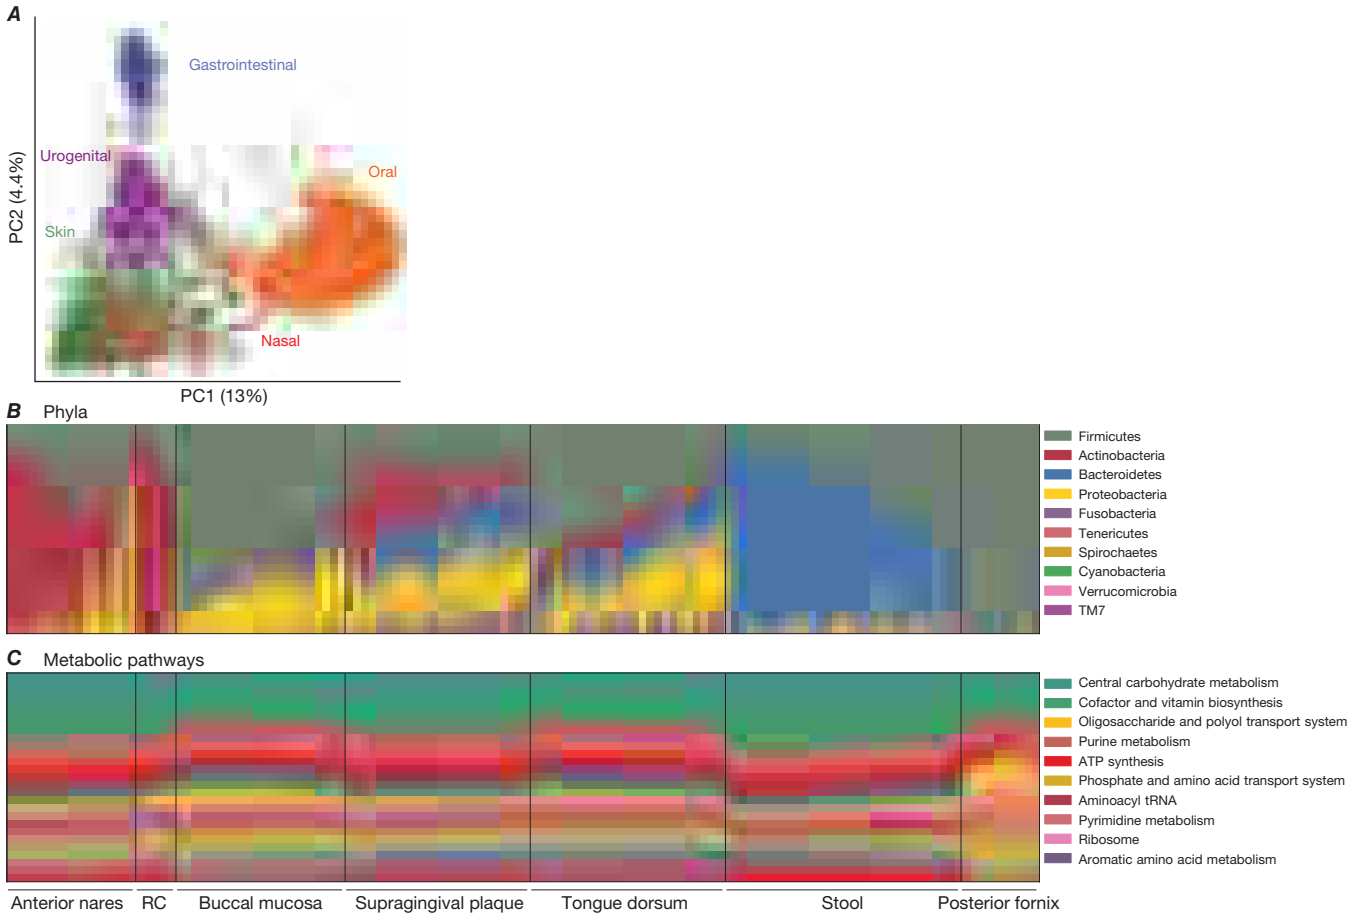

FIGURE 459-2 The human microbiome exhibits significant taxonomic variability among body sites and between individuals while maintaining core metabolic pathways. ***A.*** Principal coordinates (PC) plot showing variation among samples demonstrates that primary clustering is by body area, with the oral, gastrointestinal, skin, and urogenital habitats separate; the nares habitat bridges oral and skin habitats. Each circle represents an individual sample. ***B, C.*** Vertical bars represent microbiome samples by body habitat, with each bar within a given body site representing a different individual. Bars indicate relative abundances colored by microbial phyla (***B***) and metabolic pathways (***C***). The legend on the right indicates the most abundant phyla/pathways. Nature 486:207, 2012.)*

space (body region), and clinical conditions. Moreover, the majority of human-associated microbes are not readily cultivable—a situation that raises questions about the best methodology for such quantitation. Initial back-of-the-envelope calculations performed in the 1970s suggested that there were roughly tenfold more bacteria in the body than there were human cells. This rather astounding estimate suggested that humans are really only ~10% "human" and that by far the greatest part of the holobiont is represented by microbes. This stark numerical discrepancy has prompted some to question "who parasitizes whom." However, a more recent estimate has suggested that there are "only" ~1.3 times more bacteria in the body than there are human cells and thus that humans are ~56% "bacterial." Of note, this more recent study does not include the numbers of viruses (known to generally be approximately tenfold more abundant than other microbes), fungi, or Archaea. Given these additional microorganisms, the notion that microbes constitute >90% of the cells present in a human body is likely correct. These ratios are even starker when one considers the genetic potential of human cells versus that of commensal organisms. In contrast to the ~20,000 genes in the human genome, the estimated total number of genes in the microbiota (which together constitute the *microbiome*)—i.e., >2,000,000—indicates that the human genome contributes <1% to the total genetic potential of the overall holobiont. Most microbiome studies to date have focused almost exclusively on the bacterial component; much remains to be learned about the functional interplay of bacteria, viruses, fungi, and Archaea and how these other classes of microorganisms impact human health.

In terms of overall diversity, >10,000 different bacterial species are present in the human microbiota; the intestines alone contain >1000 species. At any given time, the body of any given individual harbors 500–1000 bacterial species, with 100–200 bacterial species in the gut alone. If one considers different strains of the same bacterial species, which may be functionally different from one another, the diversity of the microbiota is probably at least a magnitude greater. Although marked diversity exists at the strain and species level, only limited bacterial phyla are generally found in the human microbiota at any given body site **(Fig. 459-3)**.

INFLUENCES ON THE MICROBIOTA

An individual's specific microbial configuration is dynamic and is quickly altered in response to subtle changes in the microenvironments in which the bacteria reside. On a day-to-day basis, these changes usually reflect alterations in the relative abundance of the various microbes. However, some exposures have a greater effect on the microbiota and can shift the microbial population to a new equilibrium via the loss of specific species and/or the acquisition of others; this new microbial equilibrium can be associated with either health or a disease state **(Fig. 459-4)**. Identification of the factors that influence the microbiota's composition is critical to an understanding of what leads to and controls intra- and inter-individual variation. Moreover, an understanding of the influences on the microbiota will facilitate the design and proper interpretation of microbiota studies. While it is clear that the microbiota can be altered through these various mechanisms, it is not yet clear whether these changes are biologically significant.

Genetics Studies of monozygotic and dizygotic twins have revealed that host genetics have a small but statistically significant effect on the microbiota's composition. Notably, some taxa, such as *Christensenella* species, are more heritable than others. Thus, some inter-individual variation may be due to underlying differences in host genetics; however, it is likely that other factors explain more of the observed variability. That said, the host's genetic contribution to the microbiota, albeit small, may be meaningful. Studies in mice have demonstrated that genetic variation in the major histocompatibility complex, a specific set of immune-related genes, leads to changes in the microbiota that alter susceptibility to an autoimmune disease. These studies offer a proof of concept for the notion that the genetic predisposition observed for certain diseases may actually be mediated by indirect alterations in the microbiota.

Age Burgeoning evidence now indicates that microbial exposure begins in utero: bacterial DNA has been identified in otherwise healthy placentas, in amniotic fluid obtained at early stages of gestation, and in meconium of term newborns. Although some controversy persists about whether these results reflect contamination and/or the presence of nonviable bacteria, they raise the possibility that human exposure to the microbial world begins before birth. The delivery mode (vaginal versus cesarean section) and the method of feeding (breast milk versus formula, timing of solid food introduction) are major determinants of an infant's early microbiota. After birth, the infant's microbiota goes through a stereotyped succession process; with increases in bacterial diversity and functional capacity, the child's microbiota resembles that of an adult by the age of 2–3 years. Cross-sectional studies that have examined the microbiota across the entire age spectrum have revealed a general stability of the fecal microbiota after 2–3 years of age; however, the microbiota of the elderly (persons >80 years of age) demonstrates notable differences from those of their younger counterparts, with increases in *Bacteroides* and *Eubacterium* species and decreases in the bacterial family Lachnospiraceae.

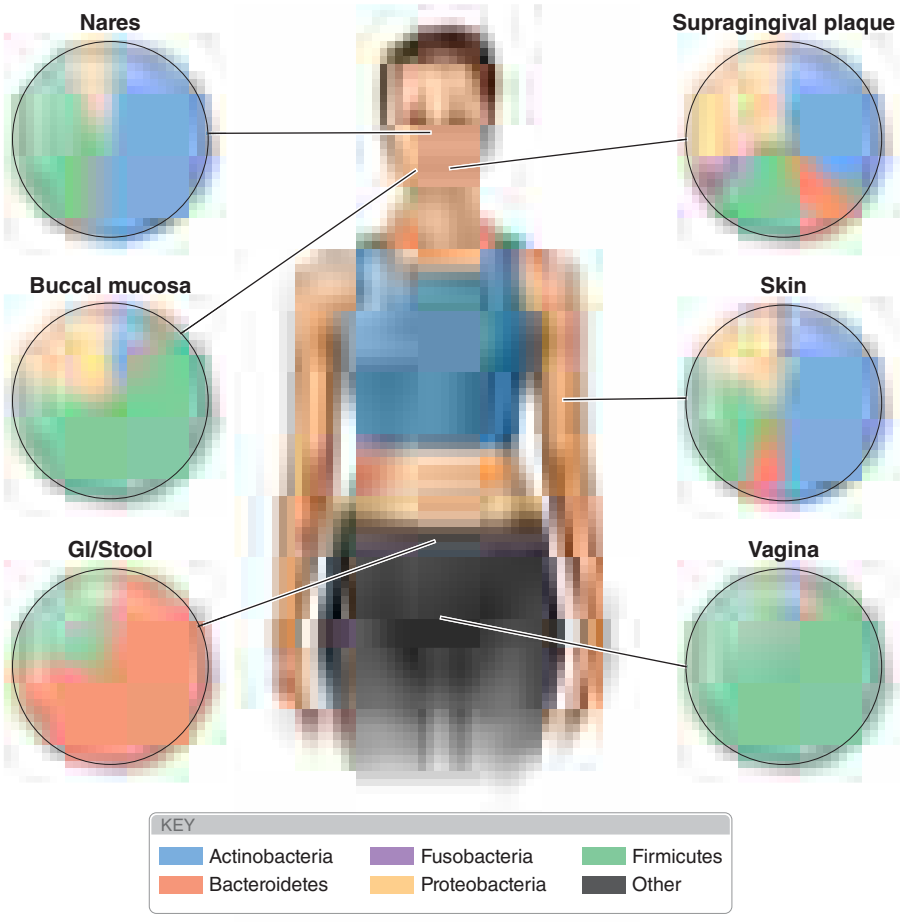

FIGURE 459-3 Different anatomic sites harbor very different microbiomes. The figure indicates the relative proportion of sequences determined at the taxonomic phylum level at six anatomic sites. *(Data for stool, vagina, nares, buccal mucosa, and supragingival plaque are from the Human Microbiome Project; data for the skin is from EA Grice et al: Topographical and temporal diversity of the human skin microbiome. Science 324:1190, 2009.)*

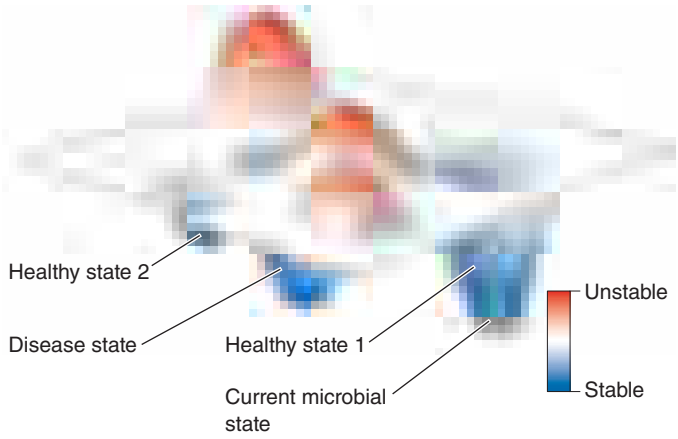

FIGURE 459-4 A stability landscape of the human microbial ecosystem. A stable state, illustrated as a depression in the landscape, can be associated with either a healthy state or a disease state. The topology of an individual's landscape reflects that person's genetics, age, diet, medications, medical history, and lifestyle. The position of the green ball represents the current microbial state. Clinical changes (e.g., administration of antibiotics, development of disease) can influence both the current state and the overall topology.

Diet Diet is a strong determinant of human health. The impact of diet is mediated, in part, by its effects on the composition of the gut microbiota. This makes intuitive sense, as the human diet provides nutrients needed not only by our own cells but also by the microbes living in the alimentary tract. In young children, this dietary influence is marked by major shifts (e.g., a decrease in *Bifidobacterium* species) in the intestinal microbiota that occur at weaning and with the introduction of solid food. In adults, long-term dietary patterns are associated with relatively stable microbial compositions. However, drastic changes in short-term macronutrient availability cause rapid (within 1 day) and reproducible fluctuations in the fecal microbiota that reflect the biological processes needed to degrade and metabolize the nutrients in the new diet. For example, vegetarian diets are associated with a microbiota that has an increased ability to metabolize plant polysaccharides (e.g., *Roseburia* species, *Eubacterium rectale*, *Ruminococcus bromii*), while animal-based diets result in an increased abundance of bile-tolerant organisms (e.g., *Alistipes*, *Bilophila*, and *Bacteroides* species). At the completion of dietary interventions and the resumption of the individual's normal dietary pattern, the microbial communities revert back to their previous states, probably because the individual resumes his or her typical diet. Taken together, dietary studies confirm that the microbiota is highly adaptable and varies in relation to changes in the diet. Of note, virtually all of these studies have focused on how the diet influences the fecal microbiota. It will be interesting to determine whether dietary changes similarly influence the microbiota at nonintestinal sites.

Drugs Virtually all drugs have the capacity to change the microbiota by altering the chemical landscape in which the microorganisms live (e.g., statins, bile acid sequestrants), modulating the host's ability to recognize and react to microbes (e.g., immunosuppressants), and/or directly interfering with the microbiota's constituents (e.g., antibiotics). These potential effects have made critical interpretation of microbiota studies much more difficult. A prominent study that claimed to identify a fecal microbiota signature associated with type 2 diabetes was later found actually to have identified a signature for patients taking metformin instead; the effects of this drug on the microbiota were far greater than the effects of the disease itself. These results highlight the importance of controlling for clinical variables in microbiota studies.

Antibiotics are the most obvious and best-studied class of drugs that modulate the microbiota. Multiple groups have demonstrated that antibiotics exert a considerable effect on the gut microbiota by depleting antibiotic-sensitive strains. What is more surprising is that many strains resistant to the antibiotic tested are also eliminated. This observation highlights the intricate microbe–microbe interactions that are fundamental to maintenance of the overall microbial community. For example, treatment with ciprofloxacin, which has little to no activity against clinically relevant anaerobes, leads to a loss of roughly one-third of the bacterial taxa in the gut. This broad effect is likely mediated by the depletion of certain "keystone" species that are required for the persistence of other, unrelated species. While many of the observed antibiotic effects (e.g., loss of specific taxa) are shared across many different individuals, some effects vary greatly among people. For example, studies found that microbiota recovery following antibiotic treatment differed significantly in terms of timing and degree. The microbiota of most healthy people who received ciprofloxacin for 5 days had completely recovered within 4 weeks, whereas microbiologic changes lasted up to 6 months in other individuals. Moreover, the degree of variation was compounded by repeated antibiotic administration, with fewer individuals reverting to their baseline microbiota after a second course of ciprofloxacin given 6 months after the first. These findings are consistent with those of microbial ecology experiments, which also showed that this type of repeated disturbance leads to less predictable results.

Lifestyle Many seemingly innocuous lifestyle decisions can impact the human microbiota. For example, a person's skin and fecal microbiotas are more similar to those of their household members, regardless of genetic relatedness, than to those of residents of different households. The degree of similarity in skin microbiotas is even greater if a dog also lives in the home; in contrast, the presence of a young child does not accentuate this microbial relatedness. The presumption is that the dog serves as a more effective "vector" for transmitting microbes during its frequent direct contact with adults in the household. The type of setting in which a person lives also impacts the microbiota. Living in a rural or farm setting leads to a different fecal microbiota than living in an urban environment. Similarly, the individual's country of residence affects the microbiota. An analysis of daily fecal samples from an individual who temporarily (i.e., for a couple of months) moved from the United States to Thailand demonstrated a large shift in the fecal microbiota that coincided with arrival in Thailand and a reversion in most respects to the "American" microbial configuration upon return to the United States. These geography-driven changes probably reflect a combination of environmental and dietary differences between locations.

Circadian Rhythms Many human biological processes follow a circadian clock; aspects of physiology are tuned by external cues, including the degree and timing of ambient light, temperature, and availability of nutrients. This endogenous biological clock enables animals to efficiently adapt to changing environmental conditions. Similarly, the microbiota maintains a circadian rhythm that is linked to the host's circadian clock. If circadian oscillations are disrupted in the host, they are similarly disrupted in the microbiota, and vice versa. These bacterial vacillations occur at the level of spatial localization within the intestine, relative species abundance, and bacterial metabolite secretion. Work in the 1960s showed that mice exhibited daily periodicity of susceptibility to infection with either *S. pneumoniae* or *E. coli* lipopolysaccharide. Although the fundamental basis for this difference was not known at the time, it is likely to be related, in part, to the microbial circadian clock. Derangements of these microbial oscillations have also been linked to the development of metabolic diseases and may underlie some of the health hazards associated with shift work and jet lag.

THE MICROBIOTA AND DISEASE

THE HYGIENE HYPOTHESIS

Over the past few decades, abundant epidemiologic data have revealed an inverse correlation between exposure to microbes and the incidence of autoimmune and/or atopic diseases (Fig. 459-5). This type of epidemiologic correlation led to the proposal of the "hygiene hypothesis" in 1989. Initially, this hypothesis focused on the development of atopic diseases in young children, with the idea that these epidemiologic observations could "be explained if allergic diseases were prevented by infection in early childhood, transmitted by unhygienic contact with older siblings, or acquired prenatally from a mother infected by contact

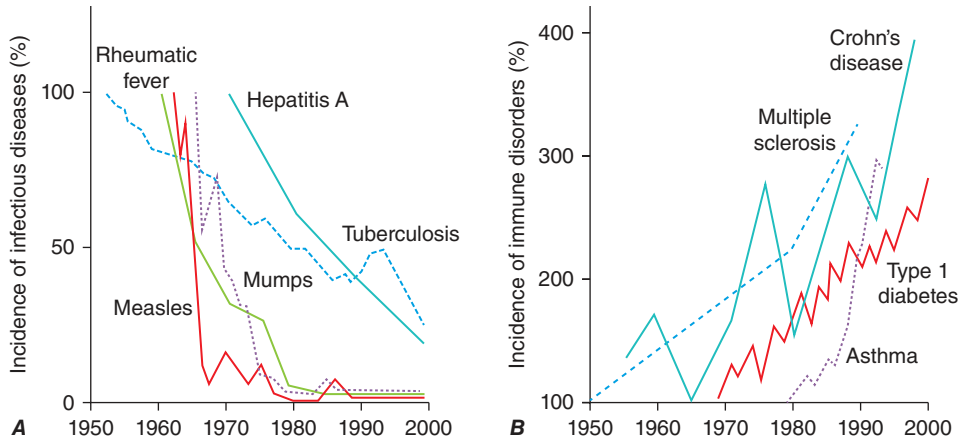

FIGURE 459-5 There was an inverse relationship between the incidence of select infectious diseases and the incidence of autoimmune disorders during the latter half of the twentieth century. *A*. Relative incidence of prototypical infectious diseases from 1950 to 2000. ***B***. Relative incidence of select autoimmune disorders from 1950 to 2000. *(From JF Bach: The effect of infections on susceptibility to autoimmune and allergic diseases. N Engl J Med 347:911, 2002. Copyright ©2002, Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

with her older children."[1] In fact, this notion that differences in living conditions and environmental exposures contribute to susceptibility to hay fever (*summer catarrh*) dates back to at least the early nineteenth century. The hygiene hypothesis has continued to evolve over the past three decades and now posits that inadequacies in microbial exposure—in combination with genetic susceptibilities—lead to a collapse of the normally highly coordinated, homeostatic immune response. At its core, the hygiene hypothesis holds that specific early-life microbial exposures are required to prevent subsequent disease and that the "Westernization" of society has led to a decrease in such exposures. This concept is now being applied beyond atopic diseases to other inflammatory and autoimmune diseases and is thought to reflect processes that occur in later life as well.

RELATIONSHIP BETWEEN THE MICROBIOTA AND SPECIFIC DISEASE STATES

The ideas inherent in the hygiene hypothesis—in sum, that microbial exposure can affect long-term health outcomes—laid the theoretical foundation for translational microbiome studies. While most of the studies described earlier sought to describe how the microbiota responds to specific and often transient influences (e.g., a course of antibiotics, dietary interventions, travel), a multitude of studies have characterized the microbiota in patients with various diseases in the hope that a better understanding of the nature of disease-specific microbial communities will provide insight into disease pathogenesis and potentially uncover novel treatment modalities. Remarkably, virtually all of these studies have demonstrated differences between the microbiotas of healthy controls and patients, irrespective of the specific disease process examined. Although it is difficult to generalize across all studies, a couple of general themes have emerged. First, disease states are typically associated with microbiotas that are less diverse than those of healthy individuals. This loss of diversity can be measured either as a decrease in the number of species (*alpha diversity*; often measured as the number of operational taxonomic units, which are the bioinformatic equivalent of species) or as a reduction in the microbial relatedness of the species present (*beta diversity*). Often, both alpha and beta diversity decrease in the setting of disease. Second, states of inflammation—regardless of site or underlying disease process—are often associated with a relative increase in the abundance of the bacterial family Enterobacteriaceae and a decrease in the abundance of Lachnospiraceae.

Dissecting Correlation and Causality Given that most of these investigations have been designed as case–control studies, it is difficult to determine whether microbiologic findings are the cause or the effect of the disease. Even studies that examine treatment-naïve patients at the time of initial diagnosis are still confounded by this "chicken or egg" issue. Moreover, prospective, longitudinal clinical studies—still rare in the microbiome field—may simply yield correlations between the microbiome and subclinical disease rather than necessarily proving causality. Experiments in animals—specifically, studies using gnotobiotic mice (germ-free mice that have been colonized with specified microbial communities)—have been critical in this regard as they allow investigation of specific differences in microbial components while controlling for the host's genetics, diet, and housing conditions. Moreover, human microbes can be transplanted into gnotobiotic mice to permit in-depth mechanistic studies of how these microbial communities affect disease pathogenesis. This marriage of human samples and animal experiments has facilitated the identification of causal roles played by some microbes in disease pathogenesis; these findings provide a critical proof of concept for the interplay of the microbiota with human health. However, the vast majority of microbiome studies are still at the level of correlation. The next several sections describe the clinical and animal data for many different disease processes. Given the voluminous and rapidly changing nature of this field, it is impossible to cover all of the disease associations known to date; rather, the following discussion represents a combination of the leading exemplars of microbiome data and nascent areas of significant clinical interest. In all cases, the hope is that further study of the role of the microbiota will provide novel diagnostics, new therapeutic modalities, and/or additional insight into disease pathogenesis.

Gastrointestinal Diseases Given that the intestines harbor the largest number and greatest diversity of organisms in the body, much work has focused on how the microbiota impacts gastrointestinal diseases. Even though the luminal surface area of the gastrointestinal tract is 30–40 square meters (~90% of which is contained within the small intestine) and features marked anatomic and functional differences that result in many discrete macro- and micro-ecosystems, stool is often used as a surrogate for the intestinal microbiota given the relative ease of collecting samples. A few studies that have compared the microbial profile in stool with the mucosa-adherent organisms present in biopsy samples have demonstrated that stool is, in fact, a reasonable proxy for biopsy samples; however, the relative microbial "noise" present in stool can sometimes overwhelm the "signal," making biopsy samples more informative for some scientific questions. The key issue is to ensure that the biopsy samples evaluated represent relatively similar intestinal regions, as there are significant differences between the organisms present in the crypt and the tip of the villus and between microbes found in the ascending versus the descending colon.

OBESITY Obesity is a worsening epidemic throughout the world, and multiple studies have linked the composition of the intestinal microbiota to the development of obesity in animal models and in humans. Indeed, many of the initial translational microbiome studies

[1] D Strachan: BMJ 299:1259, 1989.

performed in mice at the beginning of the twenty-first century focused on obesity. These early studies suggested that the ratio of the relative abundance of Bacteroidetes to Firmicutes was lower in obese mice than in control animals. Moreover, a causal relationship between the microbiota and obesity was established by the finding that gnotobiotic mice colonized with the microbiota from obese individuals had more rapid and more extensive weight gain than gnotobiotic mice colonized with the microbiota from lean individuals. Biologically, it is posited on the basis of metagenomic surveys that the obesity-associated microbiome has an increased capacity to harvest energy from the diet. Notably, the relationship between the Bacteroidetes/Firmicutes ratio and obesity did not hold in initial human studies; however, the finding that this ratio increased in obese patients who lost weight while on a fat- or carbohydrate-restricted diet suggested some generalizability between mice and humans. Beyond this ratio of major bacterial phyla, obesity was linked to a microbiome with a lower alpha diversity. Over the past ~15 years, numerous human studies examining the relationship between the microbiome and obesity have been completed, all with mixed results. A recent meta-analysis of 10 studies including nearly 3000 individuals revealed an apparent lack of relationship between the Bacteroidetes/Firmicutes ratio and obesity, though there is ~2% lower diversity associated with obesity that is statistically significant but of unclear biological significance. This finding highlights a problem common to microbiome studies: i.e., there is no sense as to what magnitude of change is biologically meaningful. Ultimately, although murine studies have indicated a causal link between the microbiota and obesity, the human data are less convincing, and their significance may be limited by the studies' having primarily examined only high-level taxonomic information rather than also assessing transcriptional or metabolic differences.

The rise in obesity has elicited a plethora of ideas about the type of diet that might be most successful in leading to sustained weight loss. It has become clear that the same dietary ingredient can have highly diverse effects on blood glucose measurements in different people and that this effect is mediated largely by the microbiome. These observations suggest that the "optimal" diet needs to be individualized in the context of the person's microbiome, which itself may continue to change over the course of the diet. An intriguing parallel question is whether the microbiota may also influence dietary preferences; such an influence would suggest important feedback loops between the microbiome and diet.

MALNUTRITION Representing the other end of the metabolic spectrum from obesity, malnutrition is also linked to an altered microbiome. Analysis of Malawian twin pairs (≤3 years of age) who were discordant for kwashiorkor—a severe form of malnutrition—revealed that kwashiorkor is associated with a microbiologically "immature" fecal microbiota that resembles that of a chronologically younger child. Transplantation of the fecal microbiota from these discordant twins into gnotobiotic mice that were fed a diet similar in composition to a typical Malawian diet established that the kwashiorkor-associated microbiome is causally related to poor weight gain. Subsequent studies demonstrated these same general trends in malnourished Bangladeshi children. Investigators were able to identify five bacterial species (*Faecalibacterium prausnitzii*, *Ruminococcus gnavus*, *Clostridium nexile*, *Clostridium symbiosum*, and *Dorea formicigenerans*) that—when administered together as a "cocktail" to mice colonized with a kwashiorkor-associated microbiome—was able to prevent growth impairments. These results demonstrate that rationally designed modulation of the murine microbiota can lead to improved health outcomes. The clinical significance of these findings for humans remains to be clarified.

INFLAMMATORY BOWEL DISEASE Ulcerative colitis and Crohn's disease, the two predominant forms of inflammatory bowel disease (IBD), are chronic gastrointestinal inflammatory conditions that differ in their locations and patterns of inflammation **(Chap. 319)**. The following observations have led to the suggestion that IBD is the result of an immune response to a dysbiotic microbiota in a genetically susceptible individual: genes account for only ~20% of susceptibility to IBD (and many of the relevant genes are related to host–microbe interactions), antibiotic treatment reduces the clinical severity of disease, and relapses of Crohn's disease are prevented by diversion of the fecal stream. While the microbiota clearly is not the only driver of disease, it is considered to be an important element. Accordingly, numerous animal and clinical studies have been designed to tease out the nature of the relationship between the microbiota and IBD.

Most of these studies have focused on comparing the microbiome's composition in IBD patients with that in healthy controls, concentrating on microbial diversity and specific bacterial taxa that are associated with health or disease. Unfortunately, few, if any, results have been universally obtained, probably because of differences in study design, inclusion criteria, and methodology (e.g., the use of stool, rectal swabs, or biopsy samples; the choice of sequencing primers; the analysis pipeline). Even with these differences among studies, patients with IBD have been shown typically to have reduced alpha and beta diversity in their fecal microbiotas. Moreover, *Clostridium* clusters IV and XIVa, which are polyphyletic and encompass several different bacterial families, are generally reduced in patients with IBD. *F. prausnitzii* is a notable example from *Clostridium* cluster IV that is often underrepresented in the stool of patients who have Crohn's disease, with more mixed results in biopsy samples. The bacterial family Lachnospiraceae, which is largely contained in *Clostridium* cluster XIVa, and other butyrate-producing organisms are also reduced in the stool of patients with IBD. Some of these species produce butyrate by using acetate generated by other members of the microbiome, and some of these acetate-producing species are similarly reduced (e.g., *Ruminococcus albus*). These complex interactions and dependencies among bacterial species pose unique challenges to definitive ascertainment of the cause–effect relationships between microbes and disease. Even before researchers were able to assess the entire microbiome at once, they often noted that patients with Crohn's disease had a higher representation of adherent invasive *E. coli* in the ileal mucosa, an observation consistent with the increased abundance of Enterobacteriaceae seen in more recent microbiome studies. Beyond bacteria, burgeoning evidence supports a role for Caudovirales bacteriophages in IBD pathogenesis, though these findings may merely reflect the underlying dysbiosis related to the loss of bacterial diversity in IBD. Moreover, some data suggest that IBD is also associated with fungal dysbiosis; several studies have demonstrated an increased ratio of Basidiomycota to Ascomycota. It is still unclear whether any of these microbial associations reflect the cause of IBD or merely serve as biomarkers of disease.

Studies of antibiotic-treated mice and gnotobiotic mice colonized with IBD-associated microbiotas have been useful in confirming that the microbiota affects colitis severity. Several bacterial species have been identified as either promoting colitis in mice (e.g., *Klebsiella pneumoniae*, *Prevotella copri*) or protecting against it (e.g., *Bacteroides fragilis*, *Clostridium* species); however, these organisms do not always correlate with the taxa identified as differentially abundant across multiple clinical studies. In contrast, IgA-coated commensal organisms isolated from patients with IBD promote more severe colitis in mice than either IgA-uncoated bacteria from patients with IBD or IgA-coated bacteria from healthy controls. These data suggest that functional categorization of the microbiota based on immune recognition (e.g., IgA coating) may be a useful approach for identifying pathogenic organisms.

Cardiovascular Disease Inflammation helps drive the pathogenesis of atherosclerosis, and it has long been postulated that microbes are involved in the atherosclerotic process. Early work demonstrated that patients with cardiovascular disease have higher titers of antibody to *Chlamydia pneumoniae* than control patients, that *C. pneumoniae* is present within atherosclerotic lesions, and that *C. pneumoniae* can both initiate and exacerbate atherosclerotic lesions in animal models. This type of analysis has been extended to other bacteria, such as *Porphyromonas gingivalis*, with the idea that multiple different bacteria may play some role in the pathogenesis of atherosclerosis.

More recent studies have demonstrated clinical correlations between serum levels of trimethylamine N-oxide (TMAO) and atherosclerotic heart disease. Given that red meat, eggs, and dairy products are important sources of carnitine and choline (both precursors of TMAO), it is not

surprising that levels of TMAO are higher in omnivores than in vegans. Animal studies have confirmed that transfer of the gut microbiota from atherosclerosis-susceptible strains of mice to atherosclerosis-resistant animals leads to increased serum levels of TMAO and a dietary choline-dependent increase in atherosclerotic plaques; this observation confirms the role of the gut microbiota in the generation of TMAO and atherosclerosis. Moreover, treatment of atherosclerosis-susceptible strains of mice with a structural analogue of choline that inhibits the first enzymatic step in TMAO formation leads to decreased circulating TMAO levels and, more importantly, restrains macrophage foam-cell formation and atherosclerotic lesion development. In a study of more than 4000 patients, plasma TMAO levels were also predictive of incident thrombosis risk (myocardial infarction, stroke). Gnotobiotic animals were used to demonstrate that this risk was dependent on the microbiota; although eight bacterial taxa were identified as being associated with both plasma TMAO levels and thrombotic risk, organisms with choline-utilization genes that represent the first step of TMAO production were not more abundant in animals at greater risk for thrombosis. This discrepancy highlights the complexity of the microbiota and suggests that other aspects of the overall dynamics of the microbial community may be in play.

Oncology Recent studies exploring the link between the microbiota and cancer have demonstrated that specific members of the microbiota can affect treatment efficacy in both a positive and a negative manner. For example, therapy with antibody to programmed cell death ligand 1 (anti-PD-L1) has proven highly effective for a number of different cancers **(Chap. 69)**; however, a significant proportion of patients do not respond even when their tumors have high PD-L1 expression levels, a prerequisite for this type of checkpoint blockade inhibition. Using a murine melanoma model, investigators showed that variations in the microbiota resulted in differences in melanoma growth, an impact that was accentuated by anti-PD-L1 therapy. Ultimately, *Bifidobacterium* species were bioinformatically associated with improved anti-tumor responses, and administration of a "cocktail" of *Bifidobacterium* species (*B. bifidum*, *B. longum*, *B. lactis*, and *B. breve*) to melanoma-susceptible mice resulted in improved tumor-specific immunity and responses to anti-PD-L1 therapy. In a separate set of studies involving both patient data and animal experiments, the efficacy of therapy with antibody to cytotoxic T lymphocyte–associated antigen 4 (anti-CTLA-4) was associated with T-cell responses specific for either *Bacteroides thetaiotaomicron* or *B. fragilis*. In particular, administration of *B. fragilis* to germ-free or antibiotic-treated mice restored the normally absent anticancer response to anti-CTLA-4 therapy. While both of these examples demonstrate potentiation of anti-cancer therapies by the microbiota, other therapies can be antagonized. Some cancers, such as pancreatic ductal adenocarcinoma, contain intratumor bacteria, particularly Gammaproteobacteria, that can metabolize the chemotherapeutic agent gemcitabine and thereby contribute to the drug resistance of these tumors. Overall, these examples highlight the microbiota's critical impact—both direct and indirect—on the efficacy of drugs. Many other notable examples have been described (e.g., involving cyclophosphamide, digoxin, levodopa, and sulfasalazine), and many more likely remain to be discovered.

The application of microbiome science to hematopoietic stem cell transplantation (HSCT) is an area of expanding interest, particularly given the significant morbidity and mortality related to graft-versus-host disease (GVHD). In light of studies in the 1970s showing that germ-free mice developed less frequent and less severe gut GVHD than wild-type mice, clinicians began to use antibiotics to decontaminate the gut of patients undergoing HSCT. This decontamination approach yielded mixed results, probably because of differences in the antibiotic regimens used. The natural history of patients undergoing allogeneic HSCT includes a substantial loss of diversity in the fecal microbiota, with lower levels of bacterial diversity associated with increased mortality. Moreover, a retrospective analysis of ~850 patients undergoing allogeneic HSCT revealed that receipt of imipenem-cilastatin or piperacillin-tazobactam for neutropenic fever was associated with increased GVHD-related mortality at 5 years; this observation suggested that specific bacteria may help protect against GVHD-related mortality. More detailed analyses revealed an association between the abundance of *Blautia* species and protection against GVHD and mortality, though this correlation is still being examined with regard to its causal relationship. Despite significant interest in examining these microbial relationships with HSCT, little has yet been studied in the context of solid organ transplantation, which likely represents the next frontier of transplantation-related microbiome investigation.

Autoimmune Diseases The dramatic rise in the incidence of many autoimmune diseases over the past few decades has been far more rapid than can be explained simply by genetic factors (Fig. 459-5). It is increasingly thought that environmental triggers, including the microbiome, are partially responsible for the development of these autoimmune diseases.

TYPE 1 DIABETES Type 1 diabetes (T1D) is an autoimmune disorder characterized by T cell–mediated destruction of insulin-producing pancreatic islets **(Chap. 396)**. There is a clear genetic predisposition for the disease: ~70% of patients with T1D have human leukocyte antigen (HLA) risk alleles. However, only 3–7% of children with these risk alleles actually develop disease, an observation that suggests a role for other environmental factors. Studying a prospective, densely sampled, longitudinal cohort of at-risk, HLA-matched children from Finland and Estonia, investigators detailed changes in the microbiota prior to development of disease. Although only 4 of the 33 children studied developed T1D within the time frame of the study, a marked decrease of ~25% in alpha diversity occurred after seroconversion but before disease diagnosis. The low number of cases in this study unfortunately precluded identification of any specific disease-associated taxa. A follow-up study compared the microbiomes of a larger cohort of these high-risk northern European children with those of low-risk Russian children who lived in geographic proximity. *Bacteroides* species were more abundant in the high-risk group than in the low-risk group, particularly at early ages. This difference was postulated to be associated with an altered structure of the bacterial lipopolysaccharide to which children were exposed at a young age. It was further suggested that *Bacteroides*-derived lipopolysaccharide was not able to provide the immunogenic stimulus necessary to prevent T1D. These two studies offer attractive—though logistically complicated—options for future clinical investigations aimed at exploring the role of the microbiome. The first approach—longitudinally following individuals who are at high risk for a given disease—may provide insight into host–microbe relationships by mapping temporal changes in the microbiome with disease onset. An important caveat with this type of study, though, is that the associations identified may reflect preclinical disease rather than specifically indicating causality for any observed changes. The second approach illustrates how careful selection of study participants may offer an opportunity to uncover more meaningful associations that can subsequently be experimentally verified.

RHEUMATOID ARTHRITIS Similar to many other autoimmune diseases, rheumatoid arthritis (RA) is a multifactorial disease that comes to clinical attention after an environmental factor triggers symptoms in an individual with pre-existing autoantibodies. Multiple lines of evidence support the notion that RA pathogenesis is reliant on the microbiota, including the findings that germ-free mice do not develop symptoms in several RA models and that antibiotic treatment of mice mitigates against RA development. Several taxa (e.g., *Bacteroides* species, *Lactobacillus bifidus*, and segmented filamentous bacteria) have been implicated in promoting RA in murine models, and analysis of the fecal microbiota of patients with newly diagnosed RA have indicated that *P. copri* is a biomarker of disease. That this association with *P. copri* does not exist for chronic, treated RA or for psoriatic arthritis suggests some specificity for new-onset RA. A major limitation of this approach is that the identified association is shown to be a biomarker of disease (and, in this case, potentially of response to treatment) but no added insight is gained into a possible causal relationship between *P. copri* and RA. In fact, many of the patients with new-onset RA had no *Prevotella* detected, and several of the healthy controls had significant levels of

Prevotella. The lack of a strict concordance between the presence (or absence) of a specific taxon and a given disease state argues against a possible causal role.

MULTIPLE SCLEROSIS Epidemiologic studies of twin pairs and at-risk individuals moving between high- and low-risk geographic areas indicate that genetics plays a minor component in multiple sclerosis (MS) susceptibility relative to environmental factors. For example, in monozygotic twin pairs in which one sibling has MS, the other sibling also develops MS in only ~30% of cases. Although MS is a disease of the central nervous system (CNS), there is growing evidence of a link between MS and the microbiota, specifically that of the gut. Germ-free animals and antibiotic-treated animals display reduced disease incidence and severity in an MS model. Similarly, some clinical studies suggest improved disease outcomes in patients with MS who have been treated with minocycline, while patients treated with long-term penicillin appear to have an increased disease risk. Although several studies have compared the fecal microbiotas of healthy controls to those of patients with MS, these studies have all been relatively small and have yielded few results (if any) that are common throughout. Although work relating the microbiome to MS is ongoing, it has opened the door to exploring this link with other neurologic diseases. Already, there are animal data demonstrating links between the microbiota and both Parkinson's disease and autism, and there are clinical data assessing fecal microbiomes in relation to a variety of neurologic conditions. It is not quite clear how the gut microbiota is communicating with the CNS—i.e., whether communication takes place via bacterial metabolites that travel in the bloodstream and cross the blood–brain barrier, via migration of whole organisms into the CNS, or via feedback through the vagus nerve. Although our understanding of this brain–gut axis is still in its infancy, research in this area has elicited tremendous excitement as a tractable approach to potential treatments for these challenging diseases.

Atopic Diseases

The incidence and prevalence of allergic diseases continue to steadily increase, as do more severe clinical presentations. Life-threatening food allergies are now such a public health issue that nut-free classrooms are the norm in many cities. The development of allergic diseases often follows a stereotyped progression that begins with atopic dermatitis (AD) and continues, in order, with food allergy, asthma, and allergic rhinitis. The microbiome has been linked to all of these conditions and has the potential to modulate effects anywhere along this spectrum.

ATOPIC DERMATITIS The skin is the largest organ in the body, and its different anatomic sites (e.g., antecubital fossa, volar forearm, alar crease) represent distinct ecologic niches and harbor unique microbial communities. Moreover, given that the skin serves as a critical interface between the body and the external environment (e.g., microbes), it must be able to respond to unwanted microbes with an adequate immune response. AD is an inflammatory skin disorder involving immune dysfunction and a dysbiotic skin microbiota that is typically marked by greater abundances of *Staphylococcus aureus* and a lesser degree of bacterial diversity. Effective treatment of AD does not require complete elimination of *S. aureus* but is associated with restoration of the normal level of diversity. It is likely that this increase in bacterial diversity re-establishes normal immune homeostasis in the skin; specific members of the skin microbiota have been shown to induce protective skin-restricted immune responses. Coagulase-negative staphylococci (CoNS; primarily *S. epidermidis* and *S. hominis*) obtained from lesional and nonlesional skin of patients with AD were functionally screened and compared to CoNS from healthy controls; AD-lesional CoNS were much less often able to produce antimicrobial peptides (lantibiotics) directed against *S. aureus*. To demonstrate that these lantibiotic-producing CoNS were biologically relevant, they were incorporated into a lotion and applied to the arms of patients with AD. Surprisingly, a single application of the probiotic-laced lotion led to a decrease in the abundance of *S. aureus* recovered; no such decrease was observed when lantibiotic-negative strains were used. The authors of this study did not specifically comment on the clinical improvement of the AD lesions. Nevertheless, this is one of a limited number of studies that is beginning to extend microbiome-related findings into clinical trials.

ASTHMA Asthma is characterized by the clinical triad of airflow obstruction, bronchial hyperresponsiveness, and inflammation in the lower respiratory tract. Although the long-standing dogma was that the lungs are sterile, there is now convincing evidence for a constant ebb and flow of bacteria within the lower airways. In healthy states, the mucociliary escalator continually eliminates these bacteria soon after they land in the airways; in disease states (e.g., cystic fibrosis, chronic obstructive pulmonary disease), these bacteria establish long-term colonization of the airways and influence disease pathogenesis. In asthma specifically, both fecal and airway microbes have been linked to clinical outcomes.

Early studies of the microbiome's influence on asthma used culture-based methods to assess the hypopharyngeal microbiota of asymptomatic 1-month-old infants. Intriguingly, in one study, early-life colonization with *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, or a combination of these organisms—but not *S. aureus*—was significantly associated with persistent wheeze and asthma at 5 years of age. Eosinophilia and total IgE levels at 4 years of age were also increased in children who were neonatally colonized with these organisms. Although this study examined a fairly focused set of bacteria, it laid the experimental groundwork indicating that early-life microbial exposures influence subsequent development of asthma. A later longitudinal investigation of the fecal microbiota in a general-population birth cohort of more than 300 children demonstrated that lower abundances of the genera *Lachnospira*, *Veillonella*, *Faecalibacterium*, and *Rothia* at 3 months of age were associated with an increased risk for development of asthma. The fact that these bacterial changes were no longer apparent when the children were 1 year of age is consistent with the notion that microbial exposures early in life are important to disease pathogenesis later in life. Transplantation of stool samples from 3-month-old children at risk for asthma into gnotobiotic mice resulted in significant airway inflammation in a murine model of asthma; pre- and postnatal exposure of mice to a four-species cocktail (*F. prausnitzii*, *Veillonella parvula*, *Rothia mucilaginosa*, and *Lachnospira multipara*) inhibited airway inflammation, with a marked reduction in neutrophil numbers in bronchoalveolar lavage fluid. These data suggest that early-life modulation of the microbiome may be an effective strategy to help prevent asthma, though the specific logistics (e.g., strains, dose, timing of exposure, patient selection) remain to be clarified.

Infectious Diseases

The increased susceptibility of antibiotic-treated mice to infection with a wide range of enteric pathogens was initially observed in the 1950s and led soon thereafter to the concept of *colonization resistance*, which holds that the normal intestinal microbiota plays a critical role in preventing colonization—and therefore disease production—by invading pathogens. Seminal work in the 1970s demonstrated that this protection is largely reliant on clostridial organisms, and the subsequent half-century has been spent trying to identify the specific microbes involved. Although much of the work relating the microbiota to infection has focused on enteric pathogens, the intestinal microbiota has also been clearly linked to bacterial pneumonia in mouse models, and changes in the microbial composition of the gut have been causally related to changes in the severity of disease. Although this gut–lung axis clearly exists in animals, its relevance in humans is still unclear. Several groups are beginning to study the human lung microbiome in the context of pneumonia and tuberculosis. Moreover, the relationships between the microbiota and both systemic infections (e.g., HIV infection, sepsis) and the response to vaccination are starting to be explored.

ENTERIC INFECTIONS *Clostridium difficile* infection (CDI) represents a growing worldwide epidemic and is the leading cause of antibiotic-associated diarrhea (Chap. 129). Roughly 15–30% of patients who are successfully treated for CDI end up with recurrent disease. The strong association between antibiotic exposure and CDI initially raised the idea that the microbiota is inextricably linked to acquisition of disease,

presumably because of the loss of colonization resistance. Consistent with the epidemiologic data, characterization of the fecal microbiota of patients with CDI revealed that it is a markedly less diverse, dysbiotic community. Fecal microbiota transplantation (FMT)—the "transplantation" of stool from a healthy individual into patients with disease—was successfully used in the 1950s to treat four patients with severe CDI and has recently been demonstrated in numerous studies to be an effective therapy for recurrent CDI, with clinical cure in 85–90% of patients (as detailed below). Thus, FMT for recurrent CDI has become the "poster child" for the idea that microbiome-based therapies may transform the management of many diseases previously considered to be refractory to medical therapy. Although FMT is agnostic as to the underlying mechanism of protection, work is ongoing to identify specific microbes and host pathways that can protect against CDI. Studying mice with differential susceptibilities to CDI due to antibiotic-induced changes in their microbiota, investigators identified a cocktail of four bacteria (*Clostridium scindens*, *Barnesiella intestihominis*, *Pseudoflavonifractor capillosus*, and *Blautia hansenii*) that conferred protection against CDI in a mouse model. Intriguingly, treatment of mice with just *C. scindens* offered significant, though not complete, protection in a bile acid–dependent manner. Clinical data from patients who underwent HSCT also associated *C. scindens* with protection from CDI, an observation that suggests the possibility of translating these findings from mice to humans. This study provides another example of the identification of relevant bacterial factors through examination of microbial differences in populations that differ in disease risk.

Microbiome-related changes associated with *Vibrio cholerae* infection include a striking loss of diversity (largely due to *V. cholerae*'s becoming the dominant member of the microbiota) and an altered composition that rapidly follows the onset of disease. These changes, which occur in a reproducible and stereotypical manner, are reversible with treatment of the disease. This recovery phase involves a microbial succession that is similar to the assembly and maturation of the microbiota of healthy infants. In addition to *V. cholerae*, streptococcal and fusobacterial species bloom during the early phases of diarrhea, and the relative abundances of *Bacteroides*, *Prevotella*, *Ruminococcus/Blautia*, and *Faecalibacterium* species increase during the resolution phase and mark the return to a healthy adult microbiota. Analysis of these microbial changes occurring in patients with cholera and in healthy children led to the selection of 14 bacteria that were transplanted into gnotobiotic mice, which were then challenged with *V. cholerae*. Bioinformatic analysis of specific taxa changing during cholera determined that *Ruminococcus obeum* restrained *V. cholerae* growth. Subsequently, this relationship was experimentally confirmed, and the *R. obeum* quorum-sensing molecule AI-2 (autoinducer 2) was found to be responsible for restricting *V. cholerae* colonization via an unclear mechanism. These studies highlight the potential for use of microbiome-based therapies to prevent and/or treat infectious diseases. Moreover, they suggest that temporal analysis of longitudinal microbiome data may be an effective strategy for identifying microbes with causal relationships to disease.

HIV INFECTION The augmentation of HIV pathogenesis by some viral, bacterial, and parasitic co-infections suggests that a patient's underlying microbial environment can influence the severity of HIV disease. Moreover, it has been hypothesized that the intestinal immune system plays a significant role in regulating HIV-induced immune activation; this seems particularly likely since the intestines are an early site for viral replication and exhibit immune defects before peripheral CD4+ T cell counts decrease. Several studies have examined the intestinal microbiotas of HIV-infected individuals. Initial studies performed in nonhuman primates infected with simian immunodeficiency virus found no alteration in the bacterial components of the fecal microbiota; however, there were profound changes in the enteric virome. In contrast, many recent studies exploring this issue in patients have identified substantial differences in the HIV-associated fecal microbiota that correlate with systemic markers of inflammation. Curiously, these microbial changes do not necessarily normalize with antiretroviral therapy; this finding suggests that the microbiota may have some "memory" of the previously high HIV loads and/or that HIV infection helps reset the "normal" microbiota. This memory-like capacity of the microbiota has been demonstrated in animal models in the context of other infections and in response to dieting.

Given that the majority of new HIV transmission events follow heterosexual intercourse, there has been significant interest in examining the relationship between the vaginal microbiota and HIV acquisition. A longitudinal study of South African adolescent girls who underwent high-frequency testing for incident HIV infection facilitated the identification of bacteria that were associated with reduced risk of HIV acquisition (*Lactobacillus* species other than *L. iners*) or with enhanced risk (*Prevotella melaninogenica*, *Prevotella bivia*, *Veillonella montpellierensis*, *Mycoplasma*, and *Sneathia sanguinegens*). In mice inoculated intravaginally with *Lactobacillus crispatus* or *P. bivia*, the latter organism induced a greater number of activated CD4+ T cells in the female genital tract, a result suggesting that the increased risk of HIV acquisition associated with *P. bivia* may be secondary to the increased presence of target cells. In a separate study, the composition of the vaginal microbiota was shown to modulate the antiviral efficacy of a tenofovir gel microbicide. Although tenofovir reduced HIV acquisition by 61% in women who had a *Lactobacillus*-dominant vaginal microbiota, it reduced HIV acquisition by only 18% in women whose vaginal microbiota comprised primarily *Gardnerella vaginalis* and other anaerobes. This difference in efficacy was due to the ability of *G. vaginalis* to metabolize tenofovir faster than the target cells can take up the drug and convert it into its active form, tenofovir diphosphate. These findings illustrate how microbial ecology can be an important consideration in choosing effective treatment regimens.

RESPONSE TO VACCINATION Second only to the provision of clean water, vaccination has been the most effective public health intervention in the prevention of serious infectious diseases. Its effects are mediated by antigen-specific antibodies and, in some cases, effector T-cell responses. Although vaccines are clearly effective on a population scale, the magnitude of the immune response to vaccines can vary among individuals by tenfold to a hundredfold. Although many factors (e.g., genetics, maternal antibody levels, prior antigen exposures) can affect vaccine immunogenicity, the microbiota is now recognized as another important factor. Analysis of the fecal microbiotas of ~50 Bangladeshi children identified specific taxa that exhibited positive associations (e.g., *Actinomyces*, *Rothia*, and *Bifidobacterium* species) and negative associations (e.g., *Acinetobacter*, *Prevotella*, and staphylococcal species) with responses to vaccines against polio, tuberculosis (bacille Calmette-Guérin), tetanus, and hepatitis B. A study of infants from Ghana revealed an inverse relationship between the fecal abundance of Bacteroidetes and a response to the rotavirus vaccine. Moreover, the nasal microbiota has been implicated as a factor that contributes to the IgA response to live, attenuated influenza vaccines. These correlations based on clinical data have been partially confirmed in animal studies. The best example is the demonstration that the responses to non-adjuvanted viral subunit vaccines (inactivated influenza and polio vaccines) are reliant on the microbiota, whereas the responses to live or adjuvanted vaccines (live attenuated yellow fever, Tdap/alum, an HIV envelope protein/alum vaccine) are not. An interesting note is that the antibody response to inactivated influenza vaccine is dependent on recognition of the microbiota by Toll-like receptor 5, presumably via flagellin-expressing microbes. These data suggest that the microbiota may serve as an adjuvant for certain vaccine types. Confirmation of these findings in clinical settings may suggest ways to improve vaccine efficacy in the future.

MECHANISMS OF MICROBIOME-MEDIATED EFFECTS

As highlighted in the examples above, numerous associations have been made between the microbiome and various disease states. These correlations have often been established at broad taxonomic levels, with little or no insight into causality. Given that most clinical studies of these relationships have a fairly small sample size (often <100) and are simultaneously comparing numerous variables (i.e., each of the bacterial species in the microbiota is effectively a different feature being

compared), many of these studies may not be adequately powered and therefore may yield false-positive results. Testing of these correlations in animal models of disease has been critical in demonstrating a causal relationship between microbes and specific phenotypes. Because microbiome-wide association studies typically result in a long list of bacterial taxa that are correlated with a disease, it has been challenging to know which organism to test further in mechanistic studies. Moreover, even if a specific bacterial species is identified in these analyses, there is potentially enough strain-to-strain variation that the "functional" isolate may need to be recovered from the individuals studied; a publicly available representative of the species may not confer the same phenotype.

Despite all these difficulties, a handful of specific microbes have now been linked to disease effects; some examples have been mentioned above. The next layer of challenges relates to identification of the specific mechanisms that underlie these causal relationships. Successes along these lines have been more limited, but approaches are being developed to tackle the issue of defining specific bacterial factors and metabolites that are responsible for the phenotypic changes. Complicating factors are that many organisms, particularly those in the phylum Firmicutes, are not readily genetically tractable and that many of the phenotypes are not easy to assess with high-throughput screening.

BACTERIAL FACTORS

B. fragilis polysaccharide A (PSA) is perhaps the best-studied commensal-derived molecule that has been demonstrated to influence disease outcomes in mouse models. PSA—one of at least eight capsular polysaccharides expressed by *B. fragilis*—has a unique zwitterionic structure that incorporates both a positive and a negative charge within each repeating unit. Studies in which mice have been treated either with isogenic strains of *B. fragilis* that differ in PSA expression or with purified PSA have shown that PSA confers protection—prophylactically and therapeutically—against experimental colitis and MS. PSA is recognized by Toll-like receptor 2 on antigen-presenting cells, particularly plasmacytoid dendritic cells, and—in the setting of inflammation—induces interleukin 10 (IL-10)–producing regulatory T cells (Tregs) that help restrain inflammation.

B. fragilis is also the source of the only other microbiota-based bacterial factor identified thus far: an immunomodulatory glycosphingolipid that affects the numbers of invariant natural killer T (iNKT) cells. It is not clear whether these glycosphingolipids activate or inhibit iNKT cells; results have been discordant, probably because different glycosphingolipid species have been tested. Analysis of a specific purified glycosphingolipid (Bf717) demonstrated that it inhibits endogenous iNKT cell agonists in vitro and in vivo. Treatment of neonatal mice with Bf717 leads to a decreased number of colonic iNKT cells in adulthood and to improved outcomes in a model of colitis.

BACTERIAL METABOLITES

The use of mass spectrometry to detect and profile tens of thousands of different metabolites present in different bodily fluids has offered the promise of deeper insight into microbially mediated processes that underlie disease susceptibility. However, the fact that the overwhelming majority of these metabolites are not annotated, coupled with the sheer volume of data generated, has so far limited the general utility of these untargeted approaches. Instead, interest in more targeted approaches has increased, with a current emphasis on examining the role of short-chain fatty acids (SCFAs) and bile acids.

Short-Chain Fatty Acids Several groups have demonstrated that SCFAs, the intestinal levels of which are largely determined by bacterial metabolism, are important for the induction of Tregs, though there is not agreement on which specific SCFA (propionate, acetate, or butyrate) is most relevant. Wild-type mice colonized with bacteria known to induce colonic Tregs have elevated cecal levels of SCFAs. Colonization with any of three *Bacteroides* species (*B. caccae*, *B. massiliensis*, and *B. thetaiotaomicron*) increases levels of acetate and propionate, whereas colonization with *Parabacteroides distasonis* or a mix of 17 human-derived *Clostridium* species elevates levels of all three SCFAs. In all of these cases, though, the SCFAs inhibit histone deacetylase, with a consequent increase in Foxp3 expression. Notably, microbe-induced SCFA production has not been shown to be critical for Treg induction by any of these organisms. In contrast, there appears to be no correlation between SCFA levels and Treg numbers in mice monocolonized with various Treg-inducing bacterial species. Taken together, these data suggest important heterogeneity in the mechanisms underlying Treg development and do not rule out the possibility of other, redundant mechanisms for Treg induction.

Bile Acids Bile acids are produced in the liver but then are metabolized by intestinal bacteria to form deconjugated and secondary bile acids. These microbially produced bile acid profiles act through complex signaling pathways to balance the metabolism of lipids and carbohydrates and to affect immune responses. Therefore, bile acids are now being investigated as microbial metabolites that are critical to maintaining human health. As mentioned above, *C. scindens* helps protect mice against CDI through a bile acid–dependent process. Alterations in bile acid profiles due to underlying microbial dysbiosis have also been associated with hepatic and colonic inflammation, hepatic cellular carcinoma, colorectal cancer, and impaired gut motility. Almost all of these relationships have been documented at the level of correlation and, at best, reflect a partial change in phenotype in the setting of bile acid sequestrants (e.g., cholestyramine). Work is ongoing to determine causal relationships between bacterial metabolism of bile acids and changes in host physiology.

Other Bacterial Metabolites Although most work has thus far focused on SCFAs and bile acids, a few notable examples of other bacterial metabolites have been implicated in maintaining health. Taurine enhances NLRP6 inflammasome–induced colonic IL-18 secretion, while histamine, spermine, and putrescine suppress IL-18 secretion. Desaminotyrosine produced by *Clostridium orbiscindens* confers protection from influenza by inducing type I interferon activity. In both of these cases, the microbiota was initially shown to influence the phenotype, with either untargeted metabolomics or a more targeted screen indicating a potential role for the indicated metabolites. Given the thousands of different bacterial metabolites throughout the body, many more metabolites will undoubtedly be linked to health and disease.

MOVING MICROBIOME SCIENCE FROM BENCH TO BEDSIDE

The numerous microbiome–disease associations identified thus far have generated a great deal of hope that understanding the relevant microbe–host interactions will open the door to unlimited therapeutic applications. Microbiome-based therapies offer several potential benefits. Patients often view such treatment as more "natural" than conventional drug therapy and are therefore more likely to comply with it. Biologically, microbiome-based therapies are more likely to address one of the root causes of disease (microbial dysbiosis) rather than simply affecting the downstream sequelae. Finally, a given microbiome-based therapy may serve as a "polypill" that is effective against several different diseases stemming from similar microbial changes. Despite tremendous interest in therapeutically exploiting the microbiome, there have thus far been few clinical successes along these lines.

The most successful therapeutic application of microbiome science has been the use of FMT, particularly for CDI. As mentioned earlier, FMT involves "transplanting" stool from a healthy individual to a diseased patient, with the idea that the "healthy" microbiota will correct whatever derangement may exist in the ill patient and therefore will alleviate symptoms. Fundamentally, this notion is agnostic as to the specific microbial dysbiosis and holds that any healthy microbiota will be curative. The idea of FMT dates back to at least the fourth century, when traditional Chinese doctors used a "yellow soup" (fresh human fecal suspension) to successfully treat food poisoning and severe diarrhea. The continued use of FMT through the centuries for the treatment of diarrheal illnesses in both humans and animals, along with the growing appreciation in recent years of the importance of the microbiota, laid the groundwork for using FMT to treat CDI. Since the first major prospective trial assessing FMT for recurrent CDI in 2013, most of the numerous

studies of FMT for CDI have demonstrated remarkable efficacy, with an average clinical cure rate of ~85%. The donor stool can be fresh or frozen (use of the latter allows biobanking of samples from a limited number of pre-screened donors) and can be administered via nasogastric tube, nasoduodenal tube, colonoscopy, enema, or oral capsules; the cure rate is slightly higher with lower-gastrointestinal administration than with upper-gastrointestinal treatment. The optimal screening, preparation, and concentration of infused donor stool have not yet been determined. The most common adverse effects of FMT include altered gastrointestinal motility (with constipation or diarrhea), abdominal cramps, and bloating, all of which are generally transient and resolve within 48 h. At least 80 immunosuppressed patients have undergone FMT with no serious adverse events noted during 3 months of follow-up.

The successful use and the favorable short-term safety profile of FMT for CDI have led to its expanded application for other indications. At the end of 2017, 190 trials (listed at *ClinicalTrials.gov*) were investigating the efficacy of FMT for a range of indications, including CDI, IBD (ulcerative colitis and Crohn's disease), obesity, eradication of multidrug-resistant organisms, anxiety and depression, cirrhosis, and type 2 diabetes. The few published studies regarding indications other than CDI have generally included small sample sizes and have offered mixed results. In contrast to the successes in CDI, the results have been more varied for patients with IBD, which is perhaps the second-best-studied indication. It is not clear whether these discrepancies are due to heterogeneity in recipients (e.g., in terms of underlying disease mechanisms or endogenous microbiotas), the donor material, and/or the logistical details of FMT administration (e.g., route, frequency, dose). However, these results demonstrate that—under the right circumstances—modulation of the microbiota can be an effective therapy for IBD.

Although FMT offers an important proof of concept that microbiome-based therapies can be effective, treatment is difficult to standardize across large populations because of variability among stool donors and among the endogenous microbiotas of recipients. In addition, FMT is fraught with safety concerns, and its mechanism(s) of action are unclear. FMT likely represents the first generation of microbiome-based therapies; subsequent generations will include the use of more refined bacterial cocktails, single strains of bacteria, or bacterial metabolites as the therapeutic intervention. The field of probiotics has a complicated history: many different strains have been tested against a multitude of diseases. Several meta-analyses have combined results across bacterial strains and/or disease indications and have generally concluded that the data are not yet convincing enough to support the use of the tested regimens. It should be noted that the tested organisms have been chosen mainly on the basis of their presumed safety profile rather than in light of a plausible biological link to disease. The hope is that more focused, mechanistic microbiome studies will identify specific commensal organisms—and their underlying mechanisms of action—that are involved in disease pathogenesis and that will serve as the basis for the next wave of rationally chosen probiotics, a few of which are currently in clinical trials. The main hurdle in this endeavor has been identifying specific microbes that are causally related to protection from disease.

PERSPECTIVE

The medical view of microbes has changed radically, moving from the early-twentieth-century notion that we are engaged in a constant struggle with microbes—an "us-versus-them" mentality that focused on the necessity of eradicating bacteria—to the more recent understanding that we live in a carefully negotiated state of détente with our commensal organisms. Instead of holding a simple view of microbes as enemies to be eliminated with antibiotics, scientists are increasingly recognizing the critical role these organisms play in maintaining human health; loss of these host–microbe interactions in the increasingly sterile environment typical of Western civilization may have predisposed to the increased incidence of autoimmune and inflammatory diseases. The field of microbiome research has made great strides over the past decade in cataloguing the normal microbiota and is now on the cusp of being able to identify clinically actionable microbe–host relationships.

The recent explosion of "–omics" technologies (e.g., metagenomics, metatranscriptomics, metabolomics) has enabled the generation of vast amounts of data, but it is not yet clear how best to integrate datasets in order to gain useful insights into host–microbe relationships. The use of FMT has demonstrated that modulation of an individual's microbiota can effectively treat certain diseases; however, models with which to predict specifically how a microbiota will change after modulation—and what potentially untoward effects these changes might have—are still lacking. Implicit in this limitation is our ignorance about what microbial configuration is optimal and how a given microbiota should be rationally altered to obtain an ideal outcome.

Despite initial hyperbolic hype and a few false starts, microbiome research now stands at the precipice of an ability to treat the fundamental basis of many diseases. As the field continues to mature, it will need to move beyond correlations and address causation. The identification of causal microbes and their mechanisms of action will create a "microbial toolbox" from which relevant bioactive strains can be chosen on a per-patient basis to correct specific underlying microbial dysbioses. In the near future, our knowledge base regarding the microbiome and its relationship to health and disease will be robust enough that this information can be applied in making important treatment decisions.

460 Global Issues in Medicine

Joseph J. Rhatigan, Paul Farmer

WHY GLOBAL HEALTH?

Global health has emerged as an important field within medicine. Some scholars have defined global health as the field of study and practice concerned with improving the health of all people and achieving health equity worldwide, with an emphasis on addressing transnational problems. No single review can do much more than identify the leading problems in applying evidence-based medicine in settings of great poverty or across national boundaries. However, this is a moment of opportunity: only recently, persistent epidemics, improved metrics, and growing interest have been matched by an unprecedented investment in addressing the health problems of poor people in the developing world. To ensure that this opportunity is not wasted, the facts need to be laid out for specialists and laypeople alike. This chapter introduces the major international bodies that address health problems; identifies the more significant barriers to improving the health of people who to date have not, by and large, had access to modern medicine; and summarizes population-based data on the most common health problems faced by people living in poverty. Examining specific problems—notably HIV/AIDS **(Chap. 197)** but also tuberculosis **(Chap. 173)**, malaria **(Chap. 219)**, Ebola **(Chap. 205)**, and key "noncommunicable" chronic diseases (NCDs)—helps sharpen the discussion of barriers to prevention, diagnosis, and care as well as the means of overcoming them. This chapter closes by discussing global health equity, drawing on notions of social justice that once were central to international public health but had fallen out of favor during the last decades of the twentieth century.

A BRIEF HISTORY OF GLOBAL HEALTH INSTITUTIONS

Concern about illness across national boundaries dates back many centuries, predating the Black Plague and other pandemics. One of the first organizations founded explicitly to tackle cross-border health issues was the Pan American Sanitary Bureau, which was formed in 1902 by 11 countries in the Americas. The primary goal of what later became the Pan American Health Organization was the control of infectious diseases across the Americas. Of special concern was yellow fever, which had been running a deadly course through much of South and Central America and halted the construction of the Panama Canal. In 1948, the United Nations formed the first truly global health institution: the World Health Organization (WHO). In 1958, under the aegis of the WHO and in line with a long-standing focus on communicable diseases that cross borders, leaders in global health initiated the effort that led to what some see as the greatest success in international health: the eradication of smallpox. Naysayers were surprised when the smallpox eradication campaign, which engaged public health officials throughout the world, proved successful in 1979 despite Cold War tensions.

At the International Conference on Primary Health Care in Alma-Ata (in what is now Kazakhstan) in 1978, public health officials from around the world agreed on a commitment to "Health for All by the Year 2000," a goal to be achieved by providing universal access to primary health care worldwide. Critics argued that the attainment of this goal by the proposed date was impossible. In the ensuing years, a strategy for the provision of selective primary health care emerged. This strategy included four inexpensive interventions collectively known as GOBI: *g*rowth monitoring, *o*ral rehydration, *b*reast-feeding, and *i*mmunizations for diphtheria, whooping cough, tetanus, polio, tuberculosis, and measles. GOBI later was expanded to GOBI-FFF, which also included *f*emale education, *f*ood, and *f*amily planning. Some public health figures saw GOBI-FFF as an interim strategy to achieve "health for all," but others criticized it as a retreat from the bolder commitments of Alma-Ata.

The influence of the WHO waned during the 1980s. In the early 1990s, many observers argued that, with its vastly superior financial resources and its close—if unequal—relationships with the governments of poor countries, the World Bank had eclipsed the WHO as the most important multilateral institution working in the area of health. One of the stated goals of the World Bank was to help poor countries identify "cost-effective" interventions worthy of public funding and international support. At the same time, international financial institutions encouraged many of those nations to reduce public expenditures in health and education in order to stimulate economic growth as part of (later discredited) policies imposing restrictions as a condition for access to credit and assistance through the World Bank, the International Monetary Fund, and regional development banks. There was a resurgence of many diseases—including malaria, trypanosomiasis, and schistosomiasis—in Africa. Tuberculosis, an eminently curable disease, remained the world's leading infectious killer of adults. Half a million women per year died in childbirth during the last decade of the twentieth century, and few of the world's largest philanthropic or funding institutions focused on global health equity.

HIV/AIDS, first described in the medical literature in 1981, precipitated a change. In the United States, the advent of this newly described infectious killer marked the culmination of a series of events that dashed previous hopes of "closing the book" on infectious diseases. In Africa, which would emerge as the global epicenter of the pandemic, HIV disease strained tuberculosis control programs, and malaria continued to claim as many lives as ever: at the dawn of the twenty-first century, these three diseases alone killed nearly 6 million people each year. New research, new policies, and new funding mechanisms were called for. The past decade has seen the rise of important multilateral global health financing institutions such as the Global Fund to Fight AIDS, Tuberculosis, and Malaria; bilateral efforts such as the U.S. President's Emergency Plan for AIDS Relief (PEPFAR); and private philanthropic organizations such as the Bill & Melinda Gates Foundation. With its 193 member states and 147 country offices, the WHO remains important in matters relating to the cross-border spread of infectious diseases and other health threats. In the aftermath of the epidemic of severe acute respiratory syndrome in 2003, the WHO's International Health Regulations—which provide a legal foundation for that organization's direct investigation into a wide range of global health problems, including pandemic influenza, in any member state—were strengthened and brought into force in May 2007.

Even as attention to and resources for health problems in poor countries grow, the lack of coherence in and among global health institutions may undermine efforts to forge a more comprehensive and effective response. The WHO remains underfunded despite the ever-growing need to engage a wider and more complex range of health issues, such as the Ebola outbreak of 2014–2015 in West Africa. This may be what some have called "the golden age of global health," but leaders of major global health organizations must work together to design an effective architecture that will make the most of opportunities to link new resources for and commitments to global health equity with the emerging understanding of disease burden and the unmet need to create robust and resilient national health systems. To this end, new and old players in global health must invest heavily in *discovery* (relevant basic science), *development* of new tools (preventive, diagnostic, and therapeutic), and modes of *delivery* that will ensure the equitable provision of health products and services to all who need them.

The adoption of the Sustainable Development Goals (SDGs) in 2015 by the United Nations serves as an example of effective cooperation. The SDGs articulate 17 overarching goals across a number of domains to be achieved by 2030. Goal 3 specifically relates to global health and contains 13 distinct targets to be met, including reducing maternal and child mortality; ending the epidemics of HIV, tuberculosis, and malaria; and reducing the burden of NCDs.

Included in the SDGs is a commitment to achieve universal health coverage (UHC), providing universal access to high-quality essential health services at an affordable cost worldwide. Championed by the WHO, the World Bank, and many civil society organizations, Goal 3 will measure coverage of 16 essential health services and assess the financial burden of health spending by households in every country.

THE ECONOMICS OF GLOBAL HEALTH

Political and economic concerns have often guided global health interventions. As mentioned, early efforts to control yellow fever were tied to the completion of the Panama Canal. However, the precise nature of the link between economics and health remains a matter for debate. Some economists and demographers argue that improving the health status of populations must begin with economic development; others maintain that addressing ill health is the starting point for development in poor countries. In either case, there is increasing consensus that investments in health care delivery and the control of communicable diseases lead to increased productivity. The question is where to find the necessary resources to start the predicted "virtuous cycle."

During the past two decades, spending on health in poor countries has increased dramatically. According to a study from the Institute for Health Metrics and Evaluation (IHME) at the University of Washington, total development assistance for health worldwide grew to $36.4 billion in 2015—up from $5.6 billion in 1990. In 2015, the leading contributors included PEPFAR, the Global Fund, the GAVI Alliance, nongovernmental organizations (NGOs), the WHO, the Gates Foundation, and the World Bank, which have dramatically increased their development spending for health since 2014. It appears, however, that total development assistance for health plateaued in 2010, and it is unclear whether growth will continue in the future.

MORTALITY AND THE GLOBAL BURDEN OF DISEASE

Refining metrics is an important task for global health: only relatively recently have there been solid assessments of the global burden of disease. The first study to look seriously at this issue, conducted in 1990, laid the foundation for the first report on *Disease Control Priorities in Developing Countries* and for the World Bank's 1993 World Development Report *Investing in Health*. Those efforts represented a major advance in the understanding of health status in developing countries. *Investing in Health* has been especially influential: it familiarized a broad audience with cost-effectiveness analysis for specific health interventions and with the notion of disability-adjusted life years (DALYs). The DALY, which has become a standard measure of the impact of a specific health condition on a population, combines absolute years of life lost and years lost due to disability for incident cases of a condition. (See **Fig. 460-1** and **Table 460-1** for an analysis of the global disease burden by DALYs.)

In 2012, the IHME and partner institutions began publishing results from the Global Burden of Diseases, Injuries, and Risk Factors Study 2010 (GBD 2010). GBD 2010 is the most comprehensive effort to date to produce longitudinal, globally ambitious, and comparable estimates of the burden of diseases, injuries, and risk factors. This report reflects the expansion of the available data on health in the poorest countries and of the capacity to quantify the impact of specific conditions on a population. It measures current levels and recent trends for major diseases, injuries, and risk factors worldwide. The GBD 2010 team revised and improved the health-state severity weight system, collated published data, and used household surveys to enhance the breadth and accuracy of disease burden data. Updated reports were released in 2013 and 2015. As analytic methods and data quality improve, important trends can be identified in a comparison of global disease burden estimates from 1990 to 2015.

GLOBAL MORTALITY

Of the 55.8 million deaths worldwide in 2015, 20.2% (11.3 million) were due to communicable diseases, maternal and perinatal conditions, and nutritional deficiencies—a marked decrease compared with figures for 1990, when these conditions accounted for 34% of global mortality. Among the fraction of all deaths related to communicable diseases, maternal and perinatal conditions, and nutritional deficiencies, 74.2% occurred in sub-Saharan Africa and southern Asia. While the proportion of deaths due to these conditions has decreased significantly in the past decade, there has been a dramatic rise in the number of deaths from NCDs, which constituted the top four causes of death in 2015. The leading cause of death among adults in 2015 was ischemic heart disease, accounting for 8.9 million deaths (16% of total deaths) worldwide. In high-income countries ischemic heart disease accounted for 18.0% of total deaths, and in low- and middle-income countries it accounted for 15.5%. It is noteworthy that ischemic heart disease was responsible for just 4.7% of total deaths in sub-Saharan Africa **(Table 460-2)**. In second place—causing 11.3% of global mortality—was cerebrovascular disease (ischemic and hemorrhagic stroke), which accounted for 9.0% of deaths in high-income countries, 11.9% in low- and middle-income countries, and 5.0% in sub-Saharan Africa. Although the third leading cause of death in high-income countries was lung cancer (accounting for 5.8% of all deaths), this condition did not figure among the top 25 causes in sub-Saharan Africa. Among the 10 leading causes of death in sub-Saharan Africa, six were infectious diseases, with malaria and HIV/AIDS ranking as the dominant contributors to disease burden. In high-income countries, however, only one infectious disease—lower respiratory infection—ranked among the top 10 causes of death.

The GBD 2015 found that the worldwide mortality figure among children <5 years of age dropped from 16.39 million in 1970 to 12.1 million in 1990 and to 5.8 million in 2015—a decrease that surpassed predictions. Of childhood deaths in 2015, 2.6 million (45.0%) occurred in the neonatal period. About one-third of deaths among children <5 years old occurred in southern Asia and almost one-half in sub-Saharan Africa; ~1% occurred in high-income countries.

The global burden of death due to HIV/AIDS and malaria was on an upward slope until 2004; significant improvements have since been documented. Global deaths from AIDS fell from 1.7 million in 2006 to 1.0 million in 2016, while malaria deaths dropped from 1.2 million to 730,000 over the same period. Despite these improvements, malaria and HIV/AIDS continue to be major burdens in particular regions, with global implications. Although it has only a minor impact on mortality outside sub-Saharan Africa and Southeast Asia, malaria is the fifth leading cause of death of children <5 years of age worldwide. HIV infection ranked 42nd in global DALYs in 1990 but was the 10th leading cause of disease burden in 2015, with sub-Saharan Africa bearing the vast majority of this burden (Fig. 460-1).

The world's population is living longer: global life expectancy has increased significantly over the past 45 years from 58.8 years in 1970 to 71.8 years in 2015. This demographic change, accompanied by the fact that the prevalence of NCDs increases with age, is dramatically shifting the burden of disease toward NCDs, which have surpassed communicable, maternal, nutritional, and neonatal causes. By 2015, 71.3% of total deaths at all ages and 59.7% of all DALYs were due to NCDs. Increasingly, the global burden of disease comprises conditions and injuries that cause disability rather than death.

Worldwide, although both life expectancy and years of life lived in good health have risen, years of life lived with disability have also increased. Despite the higher prevalence of diseases common in older populations (e.g., dementia and musculoskeletal disease) in developed and high-income countries, best estimates from 2015 reveal that disability resulting from cardiovascular diseases, chronic respiratory diseases, and the long-term impact of communicable diseases was greater in low- and middle-income countries. In most developing countries, people lived shorter lives and experienced disability and poor health for a greater proportion of their lives. Indeed, 47.7% of the global burden of disease occurred in southern Asia and sub-Saharan Africa, which together account for only 37.4% of the world's population.

HEALTH AND WEALTH

Clear disparities in burden of disease (both communicable and noncommunicable) across country income levels are strong indicators that poverty and health are inherently linked. Poverty remains one of the most important root causes of poor health worldwide, and the global

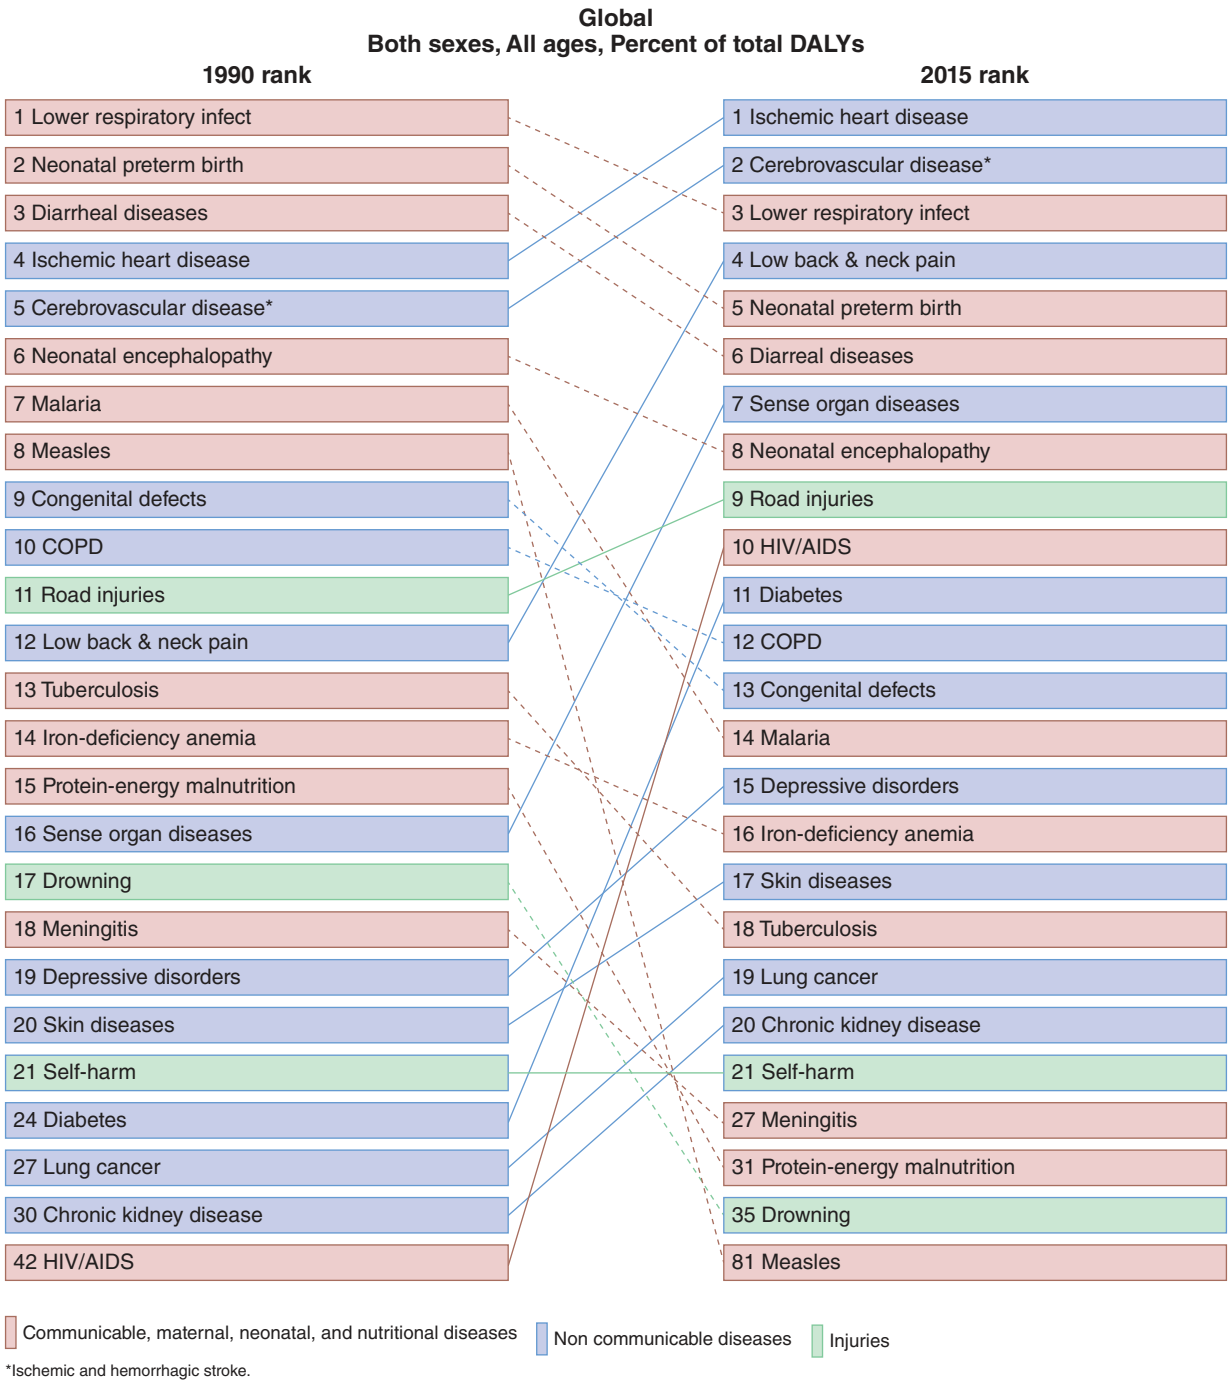

FIGURE 460-1 Global DALY (disability-adjusted life year) ranks for the top causes of disease burden in 1990 and 2015. COPD, chronic obstructive pulmonary disease. *(From the Institute for Health Metrics and Evaluation [IHME]. GBD Compare. Seattle, WA: IHME, University of Washington, 2016. Available at http://vizhub.healthdata.org/gbd-compare. Accessed July 18, 2017.)*

burden of poverty continues to be high. Among the 7.3 billion people alive in 2015, 10.7% (767 million) lived on <$1.90 (U.S.) per day—one standard measurement of extreme poverty—and another 1 billion lived on <$3.10 per day. Approximately 385 million children—19.5% of all children in low-income countries—lived in extreme poverty in 2013. Comparison of national health indicators with gross domestic product per capita among nations shows a clear relationship between higher gross domestic product and better health, with only a few outliers. Numerous studies have also documented the link between poverty and health within nations as well as across them.

RISK FACTORS FOR DISEASE BURDEN

The GBD study found that the three leading risk factors for global disease burden in 2015 were (in order of frequency) high blood pressure, tobacco smoking (including secondhand smoke), and high fasting plasma glucose—a substantial change from 1990, when childhood undernutrition was ranked first. Although ranking fifth in 2015, childhood undernutrition remains the leading risk factor for death worldwide among children <5 years of age. In an era that has seen obesity become a major health concern in many developed countries—and the fourth leading risk factor for disease burden worldwide—the persistence of undernutrition is cause for consternation. Low body weight is still the dominant risk factor for disease burden in sub-Saharan Africa. In its rural reaches, no health care initiative, however generously funded, will be effective or comprehensive without addressing undernutrition.

In a 2016 publication that examined how specific diseases and injuries are affected by environmental risk, the WHO estimated that 23% of all deaths and 26% of deaths among children <5 years of age were due to modifiable environmental factors: some 1.7 million children die every year from causes related to unhealthy environments, including

TABLE 460-1 Leading Causes of Burden of Disease (DALYs), 2015

DISEASE OR INJURY	DALYs (MILLIONS)	PERCENTAGE OF TOTAL DALYs
World	**2464.9**	**100**

the more than 360,000 deaths stemming from a lack of access to clean water and sanitation. Many of these modifiable factors lead to child and adult deaths from infectious pathologies; others lead to deaths from malignancies. Etiology and nosology are increasingly difficult to parse with regard to environmental harm. Risk factors such as indoor air pollution due to use of solid fuels, exposure to secondhand tobacco smoke, and outdoor air pollution account for 35% of lower respiratory infections globally. Various forms of unintentional injury and malaria top the list of health problems to which environmental factors contribute.

The third edition of *Disease Control Priorities in Developing Countries* (DCP3), published as a set of serial volumes based on content

area, provides evidence-based recommendations and cost-effectiveness analyses for numerous interventions, with attention to strategies for strengthening health systems. Cost-effectiveness analyses that compare relatively equivalent interventions in order to facilitate sound decisions under constraint are necessary; however, these analyses, as the DCP3 authors acknowledge, are unreliable when based on an incomplete knowledge of cost and evolving evidence of effectiveness. As both resources and objectives for global health initiatives grew, cost-effectiveness analyses (particularly those based on older evidence) sometimes steered policy makers and public health experts toward low-cost but ultimately ineffective interventions or away from higher-priced but effective ones. Thus we use the term *global health equity* to emphasize the need to ensure equitable access to high-value health interventions. To illustrate these points, it is instructive to look to HIV/AIDS, which in the course of the last four decades has become one of the world's leading infectious causes of adult death.

HIV INFECTION/AIDS

Chapter 197 provides an overview of the global HIV epidemic today. Approximately 38.8 million people worldwide were living with HIV infection in 2015; >10.3 million of those in sub-Saharan African countries were then receiving antiretroviral therapy (ART)—a two-fold increase over the corresponding figure for 2010, when ART was already the largest therapeutic rollout in the continent's history. Here the discussion will be limited to HIV/AIDS in the developing world. Lessons learned from tackling HIV/AIDS in low-resource settings are highly relevant to discussions of other chronic diseases, including NCDs, for which effective therapies have been developed. In the United States, after the mid-1990s, ART transformed HIV infection from an inescapably fatal disease into a manageable chronic illness. Across high-income countries, improved ART has dramatically prolonged life expectancy for people living with HIV infection, which now approaches that of the general population. This success rate exceeds that obtained with almost any treatment for adulthood cancer or for complications of coronary artery disease. In developing countries, treatment has been offered broadly only since 2003. Before 2003, many arguments were raised to justify not moving forward rapidly with ART programs for people living with HIV/AIDS in resource-limited settings. The standard litany included the price of therapy compared with the poverty of patients, the complexity of the intervention, the lack of infrastructure for laboratory monitoring, and the lack of trained health care providers. Narrow cost-effectiveness arguments that created false dichotomies—prevention *or* treatment rather than their synergistic integration—too often went unchallenged by policy makers, public health experts, and health economists. As a cumulative result of these delays in the face of health disparities both old and new, there were millions of premature deaths.

Disparities in access to HIV treatment did give rise to widespread moral indignation and a new type of health activism. In several middle-income countries, including Brazil, public programs have helped bridge the global access gap. Other innovative projects pioneered by international NGOs in diverse settings such as Haiti and Rwanda have established that a simple approach to ART based on intensive community engagement and social and economic support for patients and their village-based health workers can achieve remarkable results **(Fig. 460-2)**.

During the past decade, the availability of ART has increased sharply in the low- and middle-income countries that have borne the greatest burden of the HIV/AIDS pandemic. In 2000 very few people living with HIV/AIDS in these nations had access to ART, whereas by 2015 46% of people living with HIV infection were receiving ART, including 51% of people living with HIV in sub-Saharan Africa and 41% in southern Asia. It remains to be seen how many of these people are receiving ART regularly and with the requisite social support. In light of these dramatic gains, coverage targets have grown more ambitious; for example, the UNAIDS 90-90-90 Initiative aims to have 90% of people living with HIV know their status, 90% of those detected treated with ART, and 90% of those on treatment achieving viral load suppression by 2020.

This scale-up was made possible by a number of developments: a staggering drop in the cost of generically manufactured ART, the development of a standardized approach to treatment, substantial investments by funders, and the political commitment of governments to afford ART as a public good. Civil-society AIDS activists spurred many of these efforts.

Starting in the early 2000s, a combination of factors, including work by the Clinton Foundation HIV/AIDS Initiative and Médecins Sans Frontières, led to the availability of generic ART medications. While first-line ART cost more than $10,000 per patient per year in 2000, first-line regimens in low- and middle-income countries are now available for <$100 per year. At the same time, fixed-dose combinations made multidrug regimens easier to administer. Also around this time, the WHO began advocating a public health approach to the treatment of people with AIDS in low-resource settings; this approach promised—thanks to dropping viremia—to lower transmission rates and, if universally available, to end almost all mother-to-child transmission. Derived from models of care pioneered by the NGO Partners in Health and other groups, this approach proposed the use of standard first-line treatment regimens based on a simple five-drug formulary, with a more complex (and more expensive) set of second-line options in reserve. Clinical protocols were standardized, and intensive training packages for health professionals and community health workers were developed and implemented in many countries. Early rollout efforts were supported by new funding from the Global Fund and PEPFAR. In 2003, lack of access to ART was declared a global public health emergency by the WHO and UNAIDS, and those two agencies launched the 3 by 5 Initiative, setting an ambitious target: to have 3 million people in developing countries on treatment by the end of 2005. Many countries set corresponding national targets and have worked to integrate ART into their national AIDS programs and health systems and to harness the synergies between HIV/AIDS treatment and prevention activities. External funding to fight HIV/AIDS in such settings increased dramatically during this period and beyond, rising from $300 million in 1996 to over $10.8 billion in 2015. The integration of prevention and care led to a sharp drop in transmission—a 96% decline according to one review of the impact of ART rollout in heavily burdened countries in Africa and the Caribbean.

FIGURE 460-2 An HIV/TB-co-infected patient in Rwanda before (*left*) and after (*right*) 6 months of treatment.

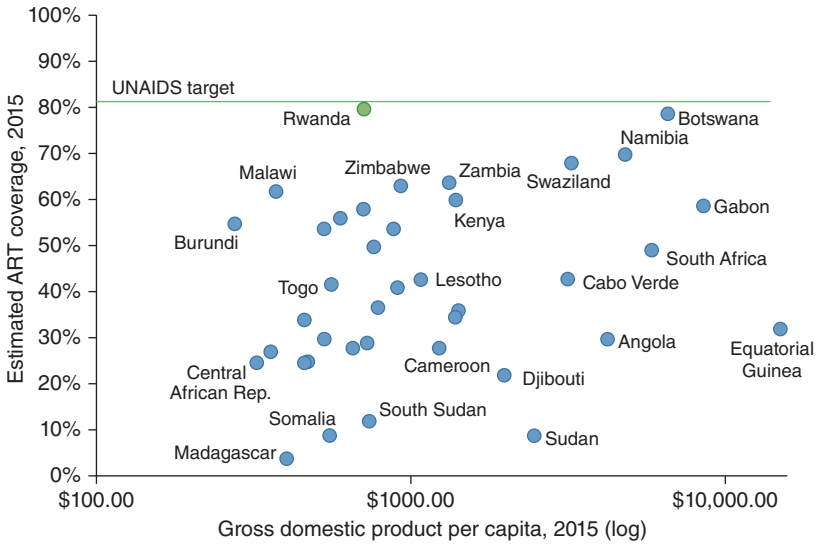

FIGURE 460-3 Antiretroviral therapy (ART) coverage (percentage of people living with HIV who received ART) in sub-Saharan Africa, 2015. *(Source: World Bank; data available through data.worldbank.org.)*

Further lessons with implications for policy and action have come from efforts now under way among lower-income countries. Rwanda provides an example: since 2000, mortality from HIV disease has fallen by >80% as the country—despite its relatively low gross national income **(Fig. 460-3)**—has provided almost universal access to ART. The reasons for this success include strong national leadership, evidence-based policy, cross-sector collaboration, community-based care, and a deliberate focus on a health-systems approach that embeds HIV/AIDS treatment and prevention in the primary health care service delivery platform. As we will discuss later in this chapter, these principles can be applied to other conditions, including NCDs.

TUBERCULOSIS

Chapter 173 provides a concise overview of the pathophysiology and treatment of tuberculosis. In 2015, an estimated 1.4 million people died from *Mycobacterium tuberculosis* infection; this figure made tuberculosis the leading infectious killer of adults globally. The disease is closely linked to HIV infection in much of the world: of the 10.4 million estimated new cases of tuberculosis in 2015, 1.2 million occurred among people living with HIV. A much more substantial proportion of the resurgence of tuberculosis registered in southern Africa is attributed to HIV co-infection. Even before the advent of HIV, however, it was estimated that fewer than one-half of all cases of tuberculosis in developing countries were ever diagnosed. Primarily because of the common failure to diagnose and treat tuberculosis, international authorities devised a single strategy to reduce the burden of disease. In the early 1990s, the World Bank, the WHO, and other international bodies promoted the DOTS strategy (*d*irectly *o*bserved *t*herapy using *s*hort-course isoniazid- and rifampin-based regimens) as highly cost-effective. Passive case-finding of smear-positive patients was central to the strategy, as was an uninterrupted drug supply.

DOTS was clearly effective for most uncomplicated cases of drug-susceptible tuberculosis, but a number of shortcomings were soon identified. First, the diagnosis of tuberculosis based solely on sputum smear microscopy—a method dating from the late nineteenth century—is not sensitive. Many cases of pulmonary tuberculosis and all cases of exclusively extrapulmonary tuberculosis are missed by smear microscopy, as are most cases of active disease in children. Second, passive case-finding relies on the availability of health care services, which is uneven in the settings where tuberculosis is most prevalent. Third, patients with multidrug-resistant tuberculosis (MDR-TB) are by definition infected with strains of *M. tuberculosis* resistant to isoniazid and rifampin; thus exclusive reliance on these drugs is unwarranted in settings in which drug resistance is an established problem.

The crisis of antibiotic resistance registered in U.S. hospitals is not confined to the industrialized world or to common bacterial infections. While the great majority of patients sick with and dying from tuberculosis are afflicted with strains susceptible to all first-line drugs, a substantial minority of patients with tuberculosis in some settings are infected with strains of *M. tuberculosis* resistant to at least one first-line antituberculosis drug. Globally in 2015, an estimated 3.9% of all patients with new *M. tuberculosis* infections and 21% of all previously treated patients were infected with MDR strains; most of these cases resulted from primary transmission. It was clear that poor infection control in hospitals and clinics in the face of delays in the initiation of effective therapy led to explosive and lethal epidemics due to these strains. To improve DOTS-based responses to MDR-TB, global health authorities adopted DOTS-Plus, which adds the diagnostics and drugs necessary to manage drug-resistant disease. Even as DOTS-Plus was being piloted in resource-constrained settings, however, new strains of extensively drug-resistant (XDR) *M. tuberculosis* (resistant to isoniazid and rifampin, any fluoroquinolone, and at least one injectable second-line drug) had already threatened the success of tuberculosis control programs in beleaguered South Africa, for example, where high rates of HIV infection had led to a doubling in the incidence of tuberculosis over the preceding decade. Gene probes of cultures of infected sputum and tissues suggest that patients may be infected by more than one strain. Despite the poor capacity for detection of MDR- and XDR-TB in most resource-limited settings, an estimated 580,000 cases of MDR-TB were thought to occur in 2015. Approximately 9.5% of these cases were caused by XDR strains.

TUBERCULOSIS AND AIDS AS CHRONIC DISEASES: LESSONS LEARNED

Strategies effective against MDR-TB have implications for the management of drug-resistant HIV infection and even drug-resistant malaria, which, through repeated infections and a lack of effective therapy, has become a chronic disease in parts of Africa (see "Malaria," below). As new therapies, whether for tuberculosis or for hepatitis C infection, become available, many of the problems encountered in the past will recur. Indeed, examining AIDS and tuberculosis as chronic diseases—instead of simply communicable ones—makes it possible to draw a number of conclusions, many of them pertinent to global health equity in general.

First, the chronic infections discussed here are best treated with multidrug regimens to which the infecting strains are susceptible. This is true of chronic infections due to many bacteria, fungi, parasites, or viruses; even acute infections such as those caused by *Plasmodium* species are not reliably treated with a single drug.

Second, charging fees for AIDS prevention and care poses insurmountable problems for people living in poverty, many of whom are unable to pay even modest amounts for services or medications. Like efforts to battle airborne tuberculosis, such services might best be seen as a public good promoting public health. Initially, a subsidy approach will require sustained donor contributions, but many African countries have set targets for increased national investments in health—a pledge that could render ambitious programs sustainable in the long run, as the Rwanda experience suggests. Meanwhile, as local investments increase, the price of AIDS care continues to decrease. The use of generic medications means that ART can now cost <$0.25 per day.

Third, the effective scale-up of pilot projects requires strengthening and sometimes rebuilding of health care systems, including those charged with delivering primary care. In the past, the lack of health care infrastructure has been cited as a barrier to providing ART in the world's poorest regions; however, AIDS resources, which are at last considerable, may be marshaled to rebuild public health systems in sub-Saharan Africa and other HIV-burdened regions—precisely the settings in which tuberculosis is resurgent. Failure to pursue such a

health-systems approach after civil wars ended in Sierra Leone and Liberia accounts for much of their extreme vulnerability to Ebola a decade later.

Fourth, the lack of trained health care personnel, most notably doctors and nurses, is incorrectly invoked as a primary reason for failure to treat AIDS in poor countries and must still be addressed. The WHO recommends a minimum of 4.45 physicians, nurses, and midwives per 1000 persons, but recent reports from that organization and others confirm that many countries, especially in sub-Saharan Africa, fall far short of those target numbers. Specifically, 44% of WHO member states reportedly have <1 physician per 1000 population. In contrast, the United States and Cuba report 2.55 and 7.52 doctors per 1000 population, respectively. Similarly, about 48% of WHO member states report having fewer than three nurses and midwives per 1000 population. Further inequalities in health care staffing exist within countries. Rural–urban disparities in health care personnel mirror disparities of both wealth and health. For instance, nearly 90% of Malawi's population lives in rural areas, but more than 95% of clinical officers work at urban facilities, and 47% of nurses work in urban tertiary-care facilities. Even community health workers trained to provide first-line services to rural populations often transfer to urban districts.

In what is termed the "brain drain," many physicians and nurses emigrate from their home countries to pursue opportunities abroad, leaving behind health systems that are understaffed and ill-equipped to deal with either emergencies like Ebola or the usual burden of disease. One reason doctors and nurses leave sub-Saharan Africa and other resource-poor areas is that they lack the tools to practice there. Funding for "vertical" (disease-specific) programs can be used not only to strengthen health systems but also to recruit and train physicians and nurses to underserved regions where they, in turn, can help to train and then work with community health workers in supervising care for patients with AIDS and many other diseases within their communities. Such training should be undertaken even where physicians are abundant, since close community-based supervision represents the highest standard of care for chronic disease, whether in developing or developed countries. The United States, which has a dearth of health care providers in many of its poor and rural communities, has much to learn from Rwanda in this regard.

Fifth, the many barriers to adequate health care and patient adherence that are raised by extreme poverty can be removed only with the deployment of "wrap-around services": food supplements for the hungry, help with transportation to clinics, child care, and housing. Extreme poverty makes it difficult for many patients to comply with therapy for chronic diseases, whether communicable or not. Experience shows, however, that these many barriers can be more readily surmounted than the extreme poverty itself to which chronic disease and acute infection contribute substantially. Indeed, poverty in its many dimensions is far and away the greatest obstacle to the scale-up of treatment and prevention services.

Finally, there is a need for a renewed basic-science commitment to the discovery and development of vaccines; more reliable, less expensive diagnostic tools; and new classes of therapeutic agents. This need applies not only to the three leading infectious killers—against none of which there is an effective vaccine—but also to most other neglected diseases of poverty.

MALARIA

Chapter 219 reviews the etiology, pathogenesis, and clinical treatment of malaria, the world's fifth-ranking infectious killer. In 2015, there were ~212 million cases of malaria, and the disease is thought to have killed 429,000 people; 70% of these deaths (~303,000) occurred among children <5 years old. The poor disproportionately experience the burden of malaria: >75% of estimated malaria deaths occur in just 13 countries, and mortality rates are highest in sub-Saharan Africa. The Democratic Republic of the Congo and Nigeria account for >36% of total estimated malaria deaths globally.

Malaria's human cost has been enormous, with the highest toll among children—especially African children—living in poverty. Macroeconomic analyses estimate that malaria may reduce the per capita gross national product of a disease-endemic country by 50% relative to that of a nonmalaria-endemic country. The causes of this drag include impaired cognitive development of children, decreased schooling, decreased savings, decreased foreign investment, and restriction of worker mobility. In light of this enormous cost, it is little wonder that an important review by the economists Sachs and Malaney concludes that "where malaria prospers most, human societies have prospered least."

Microeconomic analyses focusing on direct and indirect costs estimate that malaria may consume >10% of a household's annual income. A study in rural Kenya shows that mean direct-cost burdens vary between the wet and dry seasons (7.1% and 5.9% of total household expenditure, respectively) and that this proportion is >10% in the poorest households in both seasons. A Ghanaian study that categorized the population by income group highlighted the regressive nature of this cost: responding to malaria consumed only 1% of a wealthy family's income but 34% of a poor household's income.

In part because of differences in vector distribution and climate, resource-rich countries offer few blueprints for malaria control and treatment that are applicable in tropical (and resource-poor) settings. In 2001, African heads of state endorsed the WHO Roll Back Malaria (RBM) campaign, which prescribes strategies appropriate for sub-Saharan African countries. In 2008, the RBM partnership launched the Global Malaria Action Plan (GMAP). This strategy integrates prevention and care and calls for the avoidance of single-dose regimens and an awareness of existing drug resistance; the use of insecticide-treated bed nets (ITNs); indoor residual spraying; artemisinin-based combination therapy (ACT); intermittent preventive treatment during pregnancy; prompt diagnosis; and other vector control measures such as larviciding and environmental management.

Between 2000 and 2015, global malaria deaths were reduced by an estimated 62%, a figure equating to some 6.8 million deaths averted. Again, the experience in Rwanda is instructive: from 2000 to 2015, malaria deaths dropped by >85% for the same reasons mentioned earlier in recounting that nation's successes in battling HIV. A recent resurgence there has been linked to inadequately treated ITNs and other delivery failures, rising temperatures, and reintroduction from surrounding countries (e.g., by refugees from Burundi).

Meeting the challenge of malaria control will continue to require careful study of appropriate preventive and therapeutic strategies in the context of an increasingly sophisticated molecular understanding of pathogen, vector, and host. However, an appreciation of the economic and social devastation wrought by malaria—like that inflicted by diarrhea, AIDS, and tuberculosis—on the most vulnerable populations should heighten the level of commitment to critical analysis of ways to implement proven strategies for prevention and treatment.

Funding from the Global Fund, the Gates Foundation, the World Bank's International Development Association, and the U.S. President's Malaria Initiative, along with leadership from public health authorities, is critical to sustain the benefits of prevention and treatment. Building on the growing momentum of the last decade with adequate financial support, innovative strategies, and effective tools for prevention, diagnosis, and treatment, we may yet achieve the goal of a world largely free of malaria.

EBOLA

Chapter 205 provides an overview of the epidemiology, pathogenesis, and clinical manifestations of Ebola virus and Marburg virus infections. The 2013–2016 outbreak of Ebola virus disease in West Africa was the largest documented Ebola epidemic to date, with more than 28,000 recorded cases and 11,000 recorded deaths. Such figures underestimate the true burden, however, given inaccuracies in reporting and a growing body of evidence documenting the occurrence of minimally symptomatic Ebola virus infection.

Prior to the outbreak, the health systems of the three most affected countries—Liberia, Guinea, and Sierra Leone—were among the world's weakest. Histories of extractive colonial and postcolonial commerce, the conditional aid policies of international financial institutions, recent civil conflict, and under-resourced health ministries

left this part of West Africa bereft of the means to deliver modern medicine and promote public health. In 2013, Sierra Leone had the world's highest maternal mortality ratio, with 1460 deaths per 100,000 live births. According to one estimate, Liberia had just 51 physicians working in the entire country before the Ebola epidemic, or roughly one physician per 100,000 people. Clinics and hospitals were scarce across the region, especially in rural areas, and routinely lacked drugs, supplies, electricity, running water, laboratories, and personal protective equipment for the prevention of nosocomial infection. Such deficits were not surprising given these countries' meager public and private expenditures on health. In 2012, for example, the Guinean and Sierra Leonean governments allocated just 7 and 12% of their annual budgets, respectively, to health, according to WHO figures. Rwanda, in contrast, spent 22% of its national budget on health that year, the highest in the WHO African region.

The unprecedented scale of the recent West African Ebola epidemic was largely a symptom of these chronically weak health systems. As a result, clinicians, patients' families, and other caregivers—tasked with nursing the sick and interring the dead, but lacking the means to do so safely—faced disproportionately high risks of Ebola infection. Health facilities with poor infection control and unsafe burials served as amplifiers of transmission.

The quest to contain Ebola in West Africa was one of the largest global public health efforts in recent history, but it was far from ambitious clinically. As in previous Ebola outbreaks, preventing new infections was often prioritized over improving survival among those already infected, leading to substandard care for most West African patients and high case–fatality rates—by WHO estimates, ~70%. However, in settings in which quality supportive and critical care could be provided, clinical outcomes among Ebola-infected patients affirmed that Ebola virus disease is treatable, even in the absence of specific antiviral therapies and experimental drugs. Of the 27 Ebola patients treated in the United States and Europe in 2014 and 2015, more than 80% survived. This disparity of outcomes was also registered between European and African outbreaks of Marburg virus disease decades earlier.

As with efforts to combat AIDS and tuberculosis, the global response to Ebola reveals the unintended consequences of pitting preventive strategies against therapeutic ones—and the pull of debates about scarcity. Misguided (and often contradictory) public health messaging, distrust of disease-control and social mobilization teams, punitive containment measures, and the unavailability of safe Ebola treatment units capable of delivering effective clinical care deterred individuals from presenting to health facilities, reporting symptomatic patients and their contacts, and cooperating with epidemic response activities. The resulting epidemic of mistrust facilitated the further spread of new infections by impeding surveillance, timely diagnosis, contact tracing, and patient isolation.

The aftermath of this West African epidemic provides valuable opportunities to improve global responses to acute health crises while addressing the chronic ones that fuel them. Funds pledged to support short-term, outbreak-response operations in West Africa often went undisbursed, highlighting the paucity of measures to hold donors accountable.

Moreover, the withdrawal of humanitarian organizations and of funding earmarked solely for disease containment illustrates the inadequacies of emergency responses detached from long-term efforts to strengthen national health systems. In the absence of such systems and in the face of national economies burdened by high youth unemployment, the clinical, social, and economic needs of thousands of Ebola survivors remain vast and largely neglected. The epidemic also claimed sizeable proportions of the region's health workforce, shuttered or incapacitated health centers, and collapsed the delivery of even the modest clinical and public health interventions that had been delivered prior to Ebola's explosive spread. Yet the public sectors of Liberia, Guinea, and Sierra Leone continue to lack adequate resources to rebuild their economies and health systems: estimates as of June 2017 show that, of the roughly $9.1 billion required to finance the national and regional plans presented at a 2015 United Nations conference on Ebola recovery, only $4.5 billion was pledged, of which just 26.4% has been disbursed. It remains unclear to what extent disbursed funds have been channeled through recipient governments (or other national institutions) and whether donors and implementing partners will allow these governments the flexibility to deploy the funds to best correspond to a rapidly changing burden of disease.

"NONCOMMUNICABLE" CHRONIC DISEASES

Although the burden of communicable diseases—especially HIV infection, tuberculosis, and malaria—still accounts for the majority of deaths in resource-poor regions within sub-Saharan Africa and in the poorest reaches of several first-world cities, 71.3% of all deaths worldwide in 2015 were attributed to NCDs. Although we use this term to describe cardiovascular diseases, cancers, diabetes, and chronic lung diseases, this usage masks important distinctions. For instance, two significant NCDs in low-income countries, rheumatic heart disease (RHD) and cervical cancer, represent the chronic sequelae of infections with group A *Streptococcus* and human papillomavirus, respectively, and it is in these countries that the burden of disease due to NCDs is rising most rapidly: close to three-quarters of deaths attributable to NCDs occur in low- and middle-income countries, which also account for 82% of all early NCD-related deaths—a figure representing ~16 million people and exceeding the total number of deaths due to AIDS, tuberculosis, and malaria combined. By 2020, NCDs will account for 80% of the global burden of disease and for seven of every 10 deaths in developing countries. The recent increase in resources for and attention to communicable diseases is both welcome and long overdue, but developing countries are already carrying a "double burden" of communicable and noncommunicable diseases.

Diabetes, Cardiovascular Disease, and Cancer: A Global Perspective In contrast to tuberculosis, HIV infection, and malaria—diseases caused by single pathogens that damage multiple organs—cardiovascular diseases reflect injury to a single organ system downstream of a variety of insults, both infectious and noninfectious. Some of these insults result from rapid changes in diet and labor conditions; others are of a less recent vintage. The burden of cardiovascular disease in low-income countries represents one consequence of decades of neglect of health systems. Furthermore, cardiovascular research and investment have long focused on the ischemic conditions that are increasingly common in high- and middle-income countries.

Predictions of an imminent rise in the share of deaths and disabilities due to NCDs in developing countries have led to calls for preventive policies to improve diet, increase exercise, and restrict tobacco use, along with the prescription of multidrug regimens for persons at high-level vascular risk. Although this agenda could do much to prevent pandemic NCDs, it will do little to help persons with established heart disease stemming from nonatherogenic pathologies.

The misperception of cardiovascular diseases as a problem primarily of elderly populations in middle- and high-income countries has contributed to the neglect of these diseases by global health institutions, including regionally focused ones. Even in Eastern Europe and Central Asia, where the collapse of the Soviet Union was followed by a catastrophic surge in cardiovascular disease deaths (mortality rates from ischemic heart disease nearly doubled between 1991 and 1994 in Russia, for example), the modest flow of overseas development assistance to the health sector during these troubled years focused on the communicable causes that accounted for <1 in 20 excess deaths during that period. Even these focused investments were inadequate to halt resurgent tuberculosis (much of it caused by MDR strains), which is only now coming under control in much of the region.

DIABETES The International Diabetes Federation reports that the number of diabetic patients in the world is expected to increase from 415 million in 2015 to 642 million by 2040—nearly one in 10 adults. Already, a significant proportion of diabetic patients live in developing countries where, because those affected are far more frequently between ages 40 and 59, the complications of micro- and macrovascular disease take a far greater toll. Globally, these complications are a major cause of disability and reduced quality of life: a high fasting plasma glucose level ranks third among risks for disability and

global mortality. The GBD 2015 estimates that diabetes accounted for 1.5 million deaths in 2015; more than 80% of these deaths occurred in low- and middle-income countries.

CARDIOVASCULAR DISEASE Because systemic investigation of the causes of stroke and heart failure in sub-Saharan Africa has begun only recently, little is known about the impact of elevated blood pressure in this portion of the continent. Modestly elevated blood pressure in the absence of tobacco use in populations with low rates of obesity may confer little risk of adverse events in the short run. In contrast, persistently elevated blood pressure above 180/110 goes largely undetected, untreated, and uncontrolled in this part of the world. In the cohort of men assessed in the Framingham Heart Study, the prevalence of blood pressures above 210/120—severe hypertension—declined from 1.8% in the 1950s to 0.1% by the 1960s with the introduction of effective antihypertensive agents. Although debate continues about appropriate screening strategies and treatment thresholds, Africa's rural health centers, run largely by nurses, must quickly gain access to antihypertensive medications.

The epidemiology of heart failure also reflects inequalities in risk factor prevalence and in access to therapy. The reported burden of this condition has remained unchanged since the 1950s, but the causes of heart failure and the age of the people affected vary across the globe. Heart failure as a consequence of pericardial, myocardial, endocardial, or valvular injury accounts for as many as 5% of all medical admissions to hospitals around the world. In high-income countries, coronary artery disease and hypertension among the elderly account for most cases of heart failure. Among the world's poorest 1 billion people, however, heart failure reflects poverty-driven exposure of children and young adults to rheumatogenic strains of streptococci and cardiotropic microorganisms (e.g., HIV, *Trypanosoma cruzi*, enteroviruses, *M. tuberculosis*), untreated high blood pressure, and nutrient deficiencies. The mechanisms underlying other causes of heart failure common in these populations—such as idiopathic dilated cardiomyopathy, peripartum cardiomyopathy, and endomyocardial fibrosis—remain unclear.

In stark contrast to the extraordinary lengths to which clinicians in wealthy countries will go to treat ischemic cardiomyopathy among elderly patients, little attention has been paid to young patients with non-ischemic cardiomyopathies in resource-poor settings. Non-ischemic cardiomyopathies, such as those due to hypertension, RHD, and chronic lung disease, account for >90% of cases of cardiac failure in sub-Saharan Africa and include poorly understood entities such as peripartum cardiomyopathy (which has an incidence in rural Haiti of one per 300 live births) and HIV-associated cardiomyopathy. Lessons learned in the scale-up of chronic care for HIV infection and tuberculosis may be illustrative as progress is made in establishing the means to deliver heart-failure medications to these patients.

Some of the lessons learned from the chronic infections discussed above are, of course, relevant to cardiovascular disease, especially those classified as NCDs but caused by infectious pathogens. Integration of prevention and care remains as important today as in 1960 when Paul Dudley White and his colleagues found little evidence of myocardial infarction in the region near the Albert Schweitzer Hospital in Lambaréné, Gabon, but reported that "the high prevalence of mitral stenosis is astonishing." They termed it a duty to integrate prevention with penicillin prophylaxis and care, including medical management and surgery, when indicated. "The same responsibility," they agreed, "exists for those with correctable congenital cardiovascular defects."

RHD affects more than 30 million people worldwide, with more than 282,000 new cases each year. Among the 2.4 million cases of pediatric RHD, an estimated 42% occur in sub-Saharan Africa. This disease, which may cause endocarditis or stroke, leads to >233,000 deaths per year—almost all occurring in developing countries. A survey of acute heart failure among adults in sub-Saharan Africa showed that ~14.3% of these cases were due to RHD. Researchers in Ethiopia have reported annual death rates as high as 12.5% in rural areas. In part because the prevention of RHD has not advanced since the disease's disappearance in wealthy countries, no part of sub-Saharan Africa has eradicated RHD despite examples of success in Costa Rica, Cuba, and some Caribbean nations.

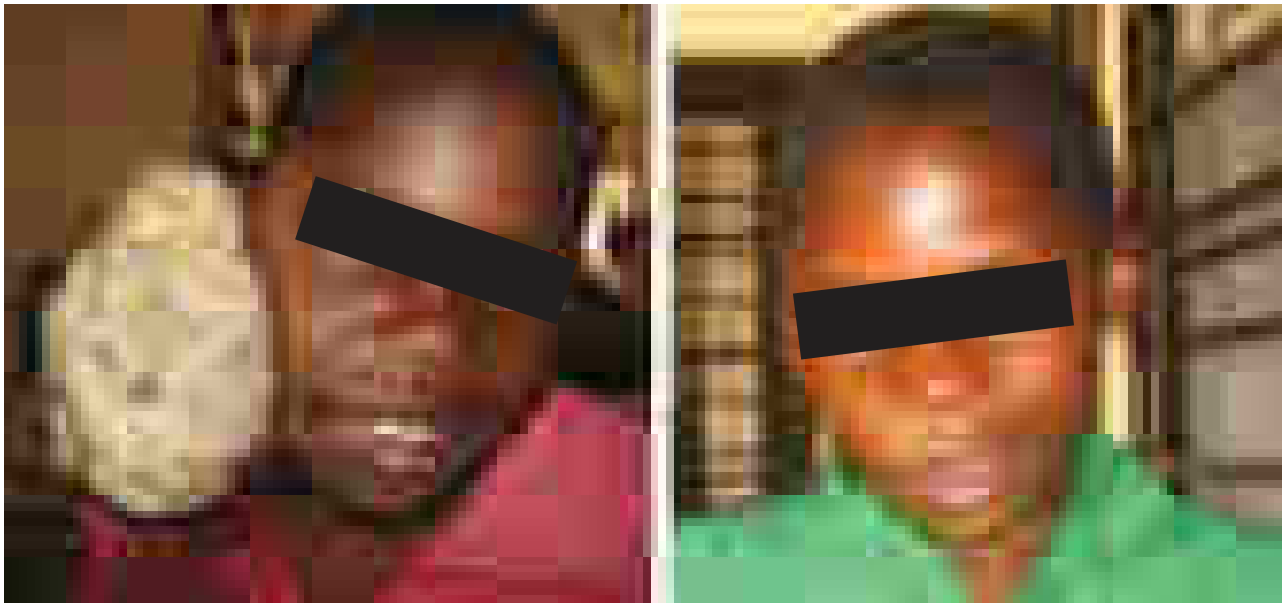
Strategies to eliminate RHD may depend on active case-finding, with confirmation by echocardiography, among high-risk groups as well as on efforts to expand access to surgical interventions among children with advanced valvular damage. Partnerships between established surgical programs and areas with limited or nonexistent facilities may help expand the capacity to provide lifesaving interventions to patients who otherwise would die early and painfully. Such partnerships can speed the further development of regional centers of excellence equipped to provide consistent, accessible, high-quality services to those now without them.

CANCER Low- and middle-income countries accounted for more than two-thirds of the 17.5 million cases and 8.7 million deaths due to cancer worldwide in 2015. By 2030, annual mortality from cancer is expected to increase by 4 million—with developing countries experiencing a sharper increase than developed nations. "Western" lifestyle changes may be responsible for the increased incidence of cancers of the breast, colon, and prostate among populations in low- and middle-income countries, but historic realities, sociocultural and behavioral factors, genetics, and poverty itself already have a profound impact on cancer-related mortality and morbidity rates. In 2012, 15.4% of the more than 14 million cases of cancer globally were attributable to infectious causes, which are responsible for <10% of cancers in developed countries but account for up to 25% of all malignancies in low- and middle-income countries. Infectious causes of cancer such as human papillomavirus, hepatitis B virus, and *Helicobacter pylori* will continue to have a much larger impact in developing countries. Environmental and dietary factors, such as indoor air pollution and high-salt diets, also contribute to increased rates of certain cancers (e.g., lung and gastric cancers). Tobacco use (both smoking and chewing) is the most important source of increased mortality rates from lung and oral cancers. In contrast to decreasing tobacco use in many developed countries, the number of smokers is growing in developing countries, especially among women and young persons.

For many reasons, outcomes of malignancies are far worse in developing countries than in developed nations. As currently funded, overstretched health systems in poor countries are not capable of early detection; at the time of tissue diagnosis, the majority of patients already have incurable malignancies. Treatment of cancers is available for only a very small number of mostly wealthy citizens in the majority of poor countries, and, even when treatment is available, the range and quality of services are often substandard. Yet this need not be the future. Fifteen years ago, MDR-TB and HIV infections were widely deemed untreatable in settings of great poverty. The feasibility of creating innovative programs that reduce technical and financial barriers to the provision of care for treatable malignancies among the world's poorest populations is now clear **(Fig. 460-4)**. Several middle-income countries, including Mexico, have expanded publicly funded cancer care to reach poorer populations. This commitment of resources has dramatically improved outcomes for cancers, from childhood leukemia to cervical cancer.

Prevention of Noncommunicable Diseases

False dichotomies, including those pitting prevention against care, persist in global health and reflect, in part, outmoded paradigms or a limited understanding of shifts in disease burden and causality as well as the dramatic variations in risk within a single nation. Moreover, such dichotomies or debates are sometimes politicized as a result of vested interests. Although globalization has had many positive effects, one negative effect has been the growth in both developed and developing countries of well-financed lobbies that have aggressively promoted unhealthy dietary changes and increased consumption of alcohol and tobacco. The WHO's 2003 Framework Convention on Tobacco Control represented a major advance, committing all of its signatories to a set of policy measures shown to reduce tobacco consumption. In 2004, the WHO released its Global Strategy on Diet, Physical Activity, and Health, which focused on population-level promotion of healthy diet and regular physical activity in an effort to reduce the growing global problem of obesity. Passing this strategy at the World Health Assembly proved difficult because of strong opposition from the food industry



A B

FIGURE 460-4 An 11-year-old Rwandan patient with embryonal rhabdomyosarcoma before (***left***) and after (***right***) 48 weeks of chemotherapy plus surgery. Eleven years later, she is healthy with no evidence of disease.

and from a number of WHO member states, including the United States. The strategy fails to focus on the NCD risk factors of the bottom billion.

The WHO estimates that 80% of all cases of cardiovascular disease and type 2 diabetes as well as 40% of all cancers can be prevented through healthier diets, increased physical activity, and avoidance of tobacco. These estimates mask large local variations. Although some evidence indicates that population-based measures can have some impact on these behaviors, it is sobering to note that increasing obesity levels have not been reversed in any population. Tobacco avoidance may be the most important and most difficult behavioral modification of all. In the twentieth century, 100 million people worldwide died of tobacco-related diseases; it is projected that >1 billion people will die of these diseases in the twenty-first century, with the vast majority of those deaths in developing countries. Today, >80% of the world's 1 billion smokers live in low- and middle-income countries. If trends continue, tobacco-related deaths will increase to 8 million per year by 2030, with 80% of those deaths in low- and middle-income countries. Investment in curbing NCDs remains disproportionately low despite the WHO's 2008–2013 Action Plan for the Global Strategy for the Prevention and Control of Noncommunicable Diseases.

MENTAL HEALTH

The WHO reports that some 676 million people worldwide suffer from depression and anxiety disorders; one in four patients visiting a health service has at least one mental, neurologic, or behavioral disorder, but most of these disorders are neither diagnosed nor treated. More than 800,000 people die by suicide every year, and major depression is the leading cause of years lost to disability in the world today. Most low- and middle-income countries devote <1% of their health expenditures to mental health.

Increasingly effective therapies exist for many of the major causes of mental disorders. One of the greatest barriers to delivery of such therapies is the paucity of skilled personnel. Most sub-Saharan African countries have only a handful of psychiatrists, for example; almost all of them practice in cities and are unavailable within the public sector or to patients living in poverty. Among the few patients who are fortunate enough to see a psychiatrist or neurologist, fewer still are able to adhere to treatment regimens: several surveys of already diagnosed patients ostensibly receiving daily therapy have revealed that, among the poor, multiple barriers prevent patients from taking their medications as prescribed. In one study from Kenya, no patients being seen in an epilepsy clinic had therapeutic blood levels of antiseizure medications, even though all had been prescribed these drugs. Moreover, many patients in this study had no detectable blood levels of these agents. The same barriers that prevent the poor from having reliable access to insulin or ART prevent them from benefiting from antidepressant, antipsychotic, and antiepileptic agents. To alleviate this problem, some authorities are proposing the training of health workers to provide community-based adherence support, counseling services, and referrals for patients in need of mental health services. One such program instituted in Goa, India, used lay counselors and resulted in a significant reduction in symptoms of common mental disorders among the target population.

CONCLUSION: TOWARD A SCIENCE OF IMPLEMENTATION

There is a long way to go before evidence-based internal medicine is applied effectively among the world's poor. Public health strategies draw largely on quantitative methods—epidemiology, biostatistics, and economics. Clinical practice, including the practice of internal medicine, draws on a rapidly expanding knowledge base and remains focused on individual patient care; clinical interventions are rarely population-based. However, global health equity depends on avoiding the false dichotomies of the past: neither public health nor clinical approaches alone are adequate to address the problems of global health. The integration of prevention and care, along with adequate funding, has shown that complex infectious diseases such as HIV/AIDS and tuberculosis are not impossible to manage, even though drug resistance and lack of effective health systems have complicated such work. Beyond what is usually termed communicable disease—i.e., in the arena of chronic diseases such as cardiovascular disease and mental illness—global health is a nascent endeavor. Efforts to address any one of these problems in settings of great scarcity need to be integrated into broader efforts to strengthen failing health systems and alleviate the growing personnel crisis within these systems. Such efforts must include the building of platforms for care delivery that are robust enough to incorporate new preventive, diagnostic, and therapeutic technologies rapidly in response to changes both in the burden of disease and in the needs not met by existing paradigms and systems of care delivery.

Academic medical centers have tried to address this "know–do" gap as new technologies are introduced and assessed through clinical trials, but the reach of these institutions into settings of poverty is limited

in rich and poor countries alike. When such centers link their capacities effectively to the public institutions charged with the delivery of health care to the poor, great progress can be made. For these reasons, scholarly work and practice in the field once known as "international health" and now often designated *global health equity* are changing rapidly. That work is still informed by the tension between clinical practice and population-based interventions, between analysis and action, and between prevention and care.

A number of university hospitals are developing training programs for physicians with an interest in global health. In medical schools across the United States and in other wealthy countries, interest in global health has exploded. One study has shown that more than 25% of medical students take part in at least one global health experience prior to graduation. Half a century or even a decade ago, such high levels of interest would have been unimaginable.

An estimated 400 million people lack access to essential health services; the consequence is millions of preventable deaths each year. An absolute majority of these premature deaths occur in Africa, with the poorer regions of Asia not far behind. They include deaths from vaccine-preventable illness, deaths during childbirth, deaths from infectious diseases that might be cured with access to antibiotics and other essential medicines, deaths from malaria that would have been prevented by ITNs and access to therapy, and deaths from waterborne illnesses. Other excess mortality is attributable to the inadequacy of efforts to develop new preventive, diagnostic, and therapeutic tools.

The development of tools must be followed quickly by their equitable distribution. Those funding the discovery and development of new tools typically neglect the concurrent need for strategies to make them available to the poor. Indeed, some would argue that the biggest challenge facing those who seek to address this outcome gap is the lack of practical means of delivery in the most heavily affected regions. When new preventive and therapeutic tools are developed without concurrent attention to delivery or implementation, one encounters what are sometimes termed "perverse effects": even as new tools are developed, inequalities of outcome—lower morbidity and mortality rates among those who can afford access, with sustained high morbidity and mortality among those who cannot—grow in the absence of an equity plan to deliver the tools to those most at risk. Preventing such a future is the most important goal of global health.

461 Worldwide Changes in Patterns of Infectious Disease

George W. Rutherford, Jaime Sepulveda

THE CONCEPT OF EMERGING INFECTIOUS DISEASES

Pathogenic organisms have been a constant companion of humans, their livestock, and their cultivated plants throughout evolution. Over the centuries, new organisms emerged as ecology changed or as humans managed to cross ecologic barriers such as oceans and mountains. Throughout history, there have been severe epidemics of infectious diseases, with devastating consequences to human populations over vast geographic regions. From the Plague of Justinian in Europe in the sixth century, to the Black Death in the fourteenth century, to the five cholera pandemics of the nineteenth century, to the 1918 Spanish influenza pandemic, to the current HIV/AIDS pandemic, the death toll in human populations has been enormous. The concept of emerging infectious diseases arose in the 1970s and 1980s with the recognition of several "new" diseases, such as legionellosis, HIV infection, Lyme disease, and toxic shock syndrome and was later expanded to include reemerging infectious diseases, such as tuberculosis. In 1991, the Institute of Medicine (IOM) convened a multidisciplinary committee to elucidate emerging microbial threats to health, with particular reference to the United States. In its report, the committee defined an emerging infectious disease as a disease "of infectious origin whose incidence in humans has either increased within the past two decades or threatens to increase in the near future." In the year following the publication of the committee's report, large outbreaks of *Escherichia coli* O157:H7 infection, cryptosporidiosis, and hantavirus pulmonary syndrome spurred the development of a national plan to recognize and interdict emerging and reemerging infectious disease threats by the Centers for Disease Control and Prevention (CDC). Since then, the list of emerging and reemerging viral, bacterial, fungal, and parasitic diseases has grown to include multiple infections and syndromes. Examples of emerging and reemerging infectious diseases, as of 2017, are shown in **Table 461-1**.

The reasons for the emergence of previously unrecognized diseases and the reemergence of diseases that have previously been largely under control are legion. At its core, however, emergence has to do with genetic changes in disease agents or changes in ecology, which includes human behavior. The IOM committee listed six primary reasons for disease emergence or reemergence: human demographics and behavior, technology and industry, economic development and land use, international travel and commerce, microbial adaptation and change, and breakdown of public health measures. A disease can emerge or reemerge for one or more of these reasons. For example, the worldwide spread of severe acute respiratory syndrome (SARS) began as a species cross-over, most likely involving transmission of a previously unknown coronavirus of horseshoe bats to Himalayan palm civets that were subsequently captured and transported to live-animal (i.e., "wet") markets in Guangzhou, China, for human consumption. The SARS coronavirus was then transmitted to humans—most likely by restaurant workers—and from them to medical personnel and eventually to individuals around the world. This spread had nothing to do with migratory patterns of bats or civets but was, instead, a consequence of human travel. The cities most effected by SARS—Hong Kong, Beijing, and Toronto—became involved because of rapid human movement via international passenger aircraft.

To this list, additional factors can now be added. Either therapeutic or acquired immunosuppression (e.g., in HIV infection) can render populations susceptible to infections that have not previously been recognized, such as that with human herpesvirus 8—the cause of Kaposi's sarcoma. Climate change, in particular, can expand the host

TABLE 461-1 Examples of Emerging and Reemerging Infectious Diseases

BACTERIAL AND RICKETTSIAL	VIRAL AND PRION	FUNGAL AND PARASITIC
Anaplasmosis	Chikungunya virus infection	Coccidioidomycosis
Anthrax	Variant Creutzfeldt-Jakob disease	*Cryptosporidium parvum* infection
Lyme disease	Dengue	*Cyclospora cayetanensis* infection
Vibrio cholerae O139 infection	Ebola virus, Marburg virus infection	Drug-resistant malaria
Diphtheria	Enterovirus D68 infection	
Ehrlichiosis	Hantavirus (Sin Nombre, Seoul) infection	
Escherichia coli O157:H7 infection	Hendra virus, Nipah virus infection	
Escherichia coli O154:H4 infection	Hepatitis C	
Legionella pneumophila infection	Hepatitis E	
Plague	HIV-1 and -2 infection	
Vancomycin-resistant *Staphylococcus aureus* infection	Human herpesvirus 6, 8 infection	
Tuberculosis	Human T-lymphotropic virus 1 and 2 infection	
	Influenza A H1N1pdm, H5N7, H7N7, H7N9	
	Lassa fever

range of disease-transmitting vectors. In addition, the weaponization of pathogenic organisms for biological terrorism or warfare can lead, at least theoretically, to prolonged chains of human-to-human transmission. One factor is clear: the preponderance of emerging infectious diseases are zoonotic in origin. The authors of a 2008 review calculated that 60.3% of all emerging infectious disease events from 1940 to 2004 were zoonotic in origin, and 71.8% of these zoonotic events originated in wildlife.

In this chapter, we review the recent changing epidemiology of four emerging infectious viral diseases that exemplify some of the IOM's principles for emergence: infections caused by West Nile virus, dengue virus, Ebola virus, and Zika virus. This list is clearly not exhaustive but highlights a few prominent instances of the recent emergence of infectious diseases and their root causes.

EXAMPLES OF EMERGING INFECTIOUS DISEASES

WEST NILE VIRUS (WNV)

WNV is a flavivirus that was originally discovered in Uganda in 1937 and emerged as a cause of neurologic disease in humans and equines. WNV exists in nature in an enzootic cycle that involves certain birds and mosquitoes, particularly those of the genera *Culex* and *Aedes*. Humans, horses, and other vertebrates are incidental hosts and, except through blood transfusion, are unlikely to transmit WNV because levels of viremia are insufficiently high to infect mosquitoes. When originally described, WNV was believed to cause a mild febrile illness, but subsequent experience showed that it caused neuroinvasive disease in some cases. The first cases of neuroinvasive disease were described in an outbreak among elderly patients in Israel and subsequently in humans and horses in the Mediterranean basin, India, and South Africa. By the 1990s, outbreaks had been reported from Romania, Russia, and Central Asia; these outbreaks were probably a result of seasonal bird migrations from endemic Mediterranean countries, with introduction of infected mosquitoes and the establishment of infection in local bird species.

An explosive outbreak of WNV infection began in the United States in the summer of 1999 and initially involved infection of birds of the family Corvidae (e.g., the American crow and blue jay) that were susceptible to neuroinvasive disease. The first human cases appeared in New York City that same summer. Subsequently, sufficient numbers of birds more resistant to neuroinvasive disease and mosquitoes of the genus *Culex* became infected and an enzootic cycle was established in North America. Over the next 3 years, WNV spread across the continental United States, Canada, and Mexico and became an important cause of human and equine neurologic disease. The WNV clade causing the North American outbreak was the same (clade 1a) as that causing disease in the Middle East, Europe, North Africa, and parts of Asia.

In 2016, 2038 cases of WNV infection in humans, including 1140 cases of neuroinvasive disease, were reported in the United States; these figures are certainly gross underestimations of the actual number of cases. There were 94 deaths, primarily among the elderly. An additional 377 cases were reported in horses from 32 states despite the availability of a reasonably protective equine vaccine. Human cases were reported from 44 states, with only Alaska, Delaware, Hawaii, Maine, New Hampshire, and West Virginia free of the disease. Infected mosquito pools were even more widespread; Maine was the only state in the continental United States to be free of all WNV activity. Thus, from an initial introduction into New York City, WNV has successfully established itself across North America and infected an estimated 2.6–6.1 million people in the United States (1.1% of the population).

Why did this happen? First, microorganisms and larger organisms, such as plants and animals, have been exchanged between the Old and New Worlds since the initial voyages of exploration in the fifteenth and sixteenth centuries. However, it is the advent of modern high-speed transportation that allows vectors, such as mosquitoes, to move between continents in hours or days as opposed to months or years. In the most likely scenario for the introduction of WNV into North America, a single viremic mosquito was accidentally transported from an area endemic for clade 1a to New York City in the cargo hold of an airplane in 1999. The original strain associated with the 1999 outbreak (NY99) had caused outbreaks in Tunisia and Israel in 1997 and 1998, respectively; this information suggests that one of those countries was the source. The imported strain in turn infected crows, which in turn infected more competent mosquitoes, establishing an enzootic life cycle in North America with at least three *Culex* species and multiple species of birds involved. This scenario represents a successful invasion of WNV into a new ecologic niche.

The likelihood that WNV will gradually disappear is low. The virus has many avian hosts and more than one mosquito vector; it has undergone at least one successful mutation in the North American outbreak, thereby becoming infectious to *Culex piperans* and *Culex tarsalis*—mosquitoes with a broad range in the western United States. Moreover, the occurrence of outbreaks in 17 consecutive years in North America suggests that WNV has been successfully introduced onto the continent and will remain endemic for years to come.

DENGUE VIRUS

Dengue is the most important of the human arboviral infections, with almost half of the world's population at risk. Occurring in the range of *Aedes* mosquitoes, dengue virus infection imposes a heavy burden of morbidity and mortality worldwide, with as many as 50–200 million infections, 500,000 severe cases, and 20,000 deaths annually. Dengue virus is a flavivirus and exists in four serotypes (DENV1–4) that

circulate independently of one another; immunity to one serotype does not confer immunity to the others.

Dengue is transmitted primarily by *Aedes aegypti* and secondarily by *Aedes albopictus*. The original life cycle of dengue virus was most likely similar to that of yellow fever, consisting of sylvatic transmission from mosquitoes to nonhuman primates and back to mosquitoes; over the past few centuries, the virus has adapted to an urban and periurban mosquito–human–mosquito cycle as well. Dengue and its more severe manifestations, dengue hemorrhagic fever and dengue shock syndrome, were first described in outbreaks in Japan in 1943 and Hawaii in 1945. However, clinically similar diseases had been reported during the previous two centuries in a geographic band extending from India south to Queensland, Australia, and east through Polynesia; in addition, there had been occasional outbreaks in areas as disparate as Greece, Panama, and southern Texas.

The ecology of dengue changed dramatically in the second half of the twentieth century, led by the successful invasion by *A. aegypti* of the global tropics after World War II, with the postwar dispersion of troops and materiel. From its ancestral roots in Southeast Asia, all four dengue serotypes spread globally in the tropics. DENV2 had been introduced into West Africa by the 1960s and established both sylvatic enzootic nonhuman primate and urban endemic human cycles. Travel and commerce facilitated importations, probably through both viremic human hosts and infected mosquitoes. In the Americas in particular, a campaign to eradicate *A. aegypti*, which is also the principal vector of yellow fever, failed in the mid-1970s, and both *A. aegypti* and dengue virus, especially DENV2, rapidly reinvaded their prior habitat; thus dengue reemerged as a major arboviral disease extending from the southern United States in the north, through northern Argentina in the south. Recent outbreaks have occurred along the U.S.–Mexico border and in the state of São Paulo in Brazil, where DENV1, DENV2, and DENV4 are co-circulating.

Dengue's emergence and spread have been intimately linked to human activity. In particular, globalization, with the movement of viremic people and mosquitoes through modern transportation of both passengers and goods, has been critical to dengue's success. One particular adaptation has also facilitated its urban spread: *Aedes* is able to breed in standing water associated with human habitation, such as cisterns, ornamental ponds, puddles, and water trapped in abandoned tires. This ability of *Aedes* has allowed dengue to be one of the only two known arboviruses (the other being Zika) that are adapted to an urban environment and can replicate entirely in a mosquito-to-human cycle. Together, these factors have led to widespread dengue transmission in a band extending across the tropics worldwide.

EBOLA AND MARBURG VIRUSES

Ebola virus is a filovirus that most likely exists in a sylvatic cycle in bats in Central and West Africa. Four strains are known to cause human disease. The first outbreak was described in Zaire in 1976. Since then, 29 outbreaks have been reported across tropical Africa, ranging in size from tens of cases to tens of thousands of cases in the West African outbreak of 2013–2016.

The life cycle of Ebola virus in the wild is not fully understood. There is evidence for sustained transmission in fruit bats, with occasional nonhuman primate spillover infections. It has been speculated that humans become infected from contact with infected bats or nonhuman primates, but, once an index case has occurred, essentially all transmission is from human-to-human contact with blood and other body fluids. Preparing bodies for burial has been an especially efficient means of transmission. In addition, health care providers who do not wear adequate personal protective equipment while caring for Ebola patients are particularly vulnerable to acquiring infection. In the West African epidemic, there was only a single zoonotic introduction and all subsequent transmission was from human to human.

The principal cause of Ebola outbreaks prior to the West African outbreak was the migration of humans into sylvatic areas, with enzootic transmission and accidental infection. In West Africa, only a single case had been recognized in Côte d'Ivoire before the 2013–2016 outbreak in the Republic of Guinea, Liberia, and Sierra Leone. It has been speculated that cultivation of palm oil attracted fruit bats, who feed on palm fruit; if so, environmental modification from dense tropical forest to palm oil plantations may have been a contributory cause. Other evidence suggests that the index patient—a 2-year-old boy—was exposed to insectivorous free-tailed bats (*Mops condylurus*). Whatever the initial event, the explosive amplification that occurred in these countries and the seven countries to which cases were exported was due to an inadequate medical and public health infrastructure. In fact, when Ebola virus was imported to countries with more functional public health systems, such as Nigeria, transmission was extinguished within three generations.

Other filovirus outbreaks have involved the transport of infected primates for medical research. The original Marburg virus outbreak, which occurred in Marburg and Frankfurt, West Germany, and Belgrade, Yugoslavia, in 1967, was likely caused by the importation of African vervet monkeys (*Cercopithecus aethiops*) from Uganda for medical research. This outbreak resulted in 31 human cases and 7 deaths. In addition, an outbreak among five crab-eating macaques (*Macaca fascicularis*) imported from the Philippines and infected with Reston Ebola virus—a strain nonpathogenic for humans—led to an epizootic in northern Virginia in 1989, eventually resulting in the culling of more than 500 primates. This outbreak, however, had no human cases associated with it, although epidemiologic investigation identified a handful of asymptomatic primate handlers who were seropositive for Reston Ebola virus. Since 1989, four additional outbreaks have been recognized in *Cynomolgus* monkeys imported from the Philippines to the United States and Italy.

A new reservoir of Ebola virus infection has now been identified: the semen of patients who have survived Ebola infection. The occurrence of several small clusters of sexually transmitted cases developing up to 284 days after symptom onset indicates prolonged carriage of Ebola virus in the testes. Moreover, the virus may remain viable over the long term in the vitreous humor.

Thus, Ebola represents a spillover event to humans and nonhuman primates from their interaction with certain species of infected and infectious bats. Contact with either the bats themselves or an infected nonhuman primate leads to infection of an index patient, which leads in turn to ongoing transmission from humans to humans. Several factors clearly contribute to the continued transmission. First, medical and public health systems are weak in severely affected countries. As experience with Ebola grows and the capacity for surveillance and response improves, numbers of secondary cases can fall; for example, in five outbreaks in Uganda stretching from 2000 to 2012, the numbers of secondary cases and the geographic spread of the outbreaks decreased with each new introduction. Second, behavioral factors contribute, in particular funeral practices that bring mourners into close contact with infectious blood and tissues during preparation of a body for burial. Third, the areas in which the initial waves of transmission occur are often remote; thus, recognition of the outbreak can be delayed and, in the case of the West African outbreak, highly mobile populations can travel to larger cities to seek care.

ZIKA VIRUS

Zika virus is a flavivirus that is transmitted by *Aedes* mosquitoes and was originally described as an infection of nonhuman primates in Uganda in 1947. The first human cases were reported in Uganda in 1962 and 1963. Zika was thought to be an illness causing a mild rash and fever in humans in tropical Africa and southern Asia. The clinical and serologic similarity of Zika infection to dengue virus infection may have led to missed outbreaks. Since 2007, an Asian lineage of Zika virus has spread from the Western Pacific (initially, Yap Island) through Polynesia and on to Easter Island, Chile, where it was documented in 2014. From Polynesia, it also spread to Brazil, most likely through viremic travelers attending the world Va'a World Sprint Championships (Polynesian canoe racing) in Rio de Janeiro in the late summer of 2014. From there, Zika virus has spread hemisphere-wide, following the host range of *A. aegypti*. Forty-eight countries in the Americas have now reported autochthonously transmitted Zika virus infections.

In tropical Africa and Asia, Zika virus is most likely transmitted in a nonhuman primate–mosquito sylvatic cycle. Other animals may be

involved in Zika's life cycle as well. A number of *Aedes* species are competent vectors, although *A. aegypti* may be the source of the majority of infections worldwide.

As Zika virus spread through Latin America and the Caribbean, a parallel epidemic of fetal microcephaly appeared; this epidemic was both temporally and geographically associated with the spread of Zika virus. More than 1.6 million cases of Zika virus infection, including 41,473 cases in pregnant women and 1950 cases of Zika-associated microcephaly, were reported from Brazil alone in 2015 and 2016. Data from a large registry of Zika-exposed pregnancies in the U.S. territories show that the overall risk of microcephaly following confirmed Zika virus infection is ~5%, ranging from 8% for infection in the first trimester to 4% for infection in the third trimester. Other fetal complications include stillbirth, neural tube defects, eye abnormalities, and sensorineural deafness. Complications in adults occur in about one of every thousand cases and include Guillain-Barré syndrome, encephalitis, leukopenia, and thrombocytopenic purpura. Moreover, it is now recognized that Zika virus can be transmitted sexually and via blood transfusion.

Thus, the introduction of Zika into the Americas represents viral invasion of a new ecosystem already widely populated by a highly competent mosquito host with an established urban habitat and an immunologically inexperienced human population. The invasion by Zika virus is in many ways similar to the original dengue invasion in the Americas in the 1950s and to the introduction of WNV into North America in 1999. Both the original importation of Zika virus and its establishment of new foci in the Americas (e.g., Florida and the Caribbean) were consequences of modern travel. Zika's spread has also been linked to climate variations, deforestation, and urban poverty.

CONTROL OF EMERGING INFECTIOUS DISEASES

Humans will continue to experience outbreaks of emerging and reemerging infectious diseases. Emerging diseases will most likely come from two sources. The first source consists of organisms that have acquired new genetic materials from other strains of the same species or from different species altogether. An example of this is influenza A virus, in which strains can acquire new genetic material through a process called *reassortment*. If the new gene is a hemagglutinin gene, the resulting reassortant virus will have a new surface hemagglutinin that is unrecognized immunologically by most human populations. An interesting case is influenza A H1N1 virus, which emerged in 2009 from the reassortment of H1N1 swine influenza virus with human seasonal H3N2 influenza virus, North American avian influenza virus, and Eurasian avian-origin swine influenza viruses. Despite a worldwide pandemic, people born before 1950 were relatively spared because they had earlier exposure to an H1N1 strain sufficiently similar to provide them with cross-immunity. Another example of this is *E. coli* O157:H7, which acquired a virulence gene from *Shigella*, probably as the result of horizontal genetic exchange. The resulting organism and several other serotypes of *E. coli* that have acquired the gene are the leading cause of hemolytic–uremic syndrome worldwide. The second source for emergence consists of existing organisms entering new ecologic niches and spreading broadly, usually through insect vectors, to immunologically naïve humans—as occurred with Zika virus. A variation on this theme is humans entering new ecosystems and becoming infected with organisms to which they have no immunity. An organism's epidemic potential will be determined by whether it is largely incapable of leaving the human host to continue onward via human-to-human transmission (e.g., *Coccidioides*) or can be efficiently transmitted from human to human (e.g., HIV and Ebola virus).

In its 1994 strategic plan to address emerging infectious disease threats, the CDC listed four goals: (1) to detect, promptly investigate, and monitor emerging pathogens, the diseases they cause, and the factors influencing their emergence; (2) to integrate laboratory science and epidemiology in order to optimize public health practice; (3) to enhance communication of public health information about emerging diseases and ensure prompt implementation of prevention strategies; and (4) to strengthen local, state, and federal public health infrastructures in order to support surveillance and implement prevention and control programs. Much of this plan has been implemented. The concept of "emerging infectious diseases" has been broadly accepted, and molecular biological methods have improved to the point that, for example, the SARS coronavirus was completely sequenced in a matter of days. In addition, there has been an increasing recognition of the "one health" concept: the nexus among human, livestock, wildlife, and plant health and the development of surveillance systems to provide early warnings of emerging and reemerging infections. New vaccines and new vector-control agents are important promising weapons in the struggle to contain existing diseases; vaccines against both dengue and Ebola have been shown to be efficacious in phase 3 trials, and a new vector-control technique involving deliberate infection of the *Aedes* population with *Wolbachia*, a bacterial genus that inhibits the transmission of arbovirus from mosquito hosts, is being evaluated.

The World Health Organization has developed new international health regulations that are designed, in part, to facilitate the recognition and reporting of infectious disease threats. However, as evidenced by the 2013–2016 Ebola virus epidemic in West Africa, additional capacity and possibly new forms of global health governance and response may be required. What is clear is that humans will continue to experience new and reemerging infections, and we will need robust, flexible, and timely responses in order to control them.

462 Primary Care and Global Health

Tim Evans, Kumanan Rasanathan

The twentieth century witnessed the rise of an unprecedented global health divide. Industrialized or high-income countries experienced rapid improvement in standards of living, nutrition, health, and health care. Meanwhile, in low- and middle-income countries with much less favorable conditions, health and health care progressed much more slowly. The scale of this divide is reflected in the current extremes of life expectancy at birth, with Japan at the high end (85 years) and Chad at the low end (50 years). This 35-year difference reflects the daunting range of health challenges faced by low- and middle-income countries. These nations must deal not only with a complex mixture of diseases (both infectious and chronic) and illness-promoting conditions but also, and more fundamentally, with the fragility of the foundations underlying good health (e.g., sufficient food, water, sanitation, and education) and of the systems necessary for universal access to good-quality health care. In the last decades of the twentieth century, the need to bridge this global health divide and establish health equity was increasingly recognized. The Declaration of Alma Ata in 1978 crystallized a vision of justice in health, regardless of income, gender, ethnicity, or education, and called for "health for all by the year 2000" through primary health care. While much progress has been made since the declaration, at the end of the first decade and half of the

twenty-first century, much remains to be done to achieve global health equity.

This chapter looks first at the nature of the health challenges that underlie the health divide in low- and middle-income countries. It then outlines the values and principles of a primary health care approach, with a focus on primary care services. Next, the chapter reviews the experience of low- and middle-income countries in addressing health challenges through primary care and a primary health care approach. Finally, the chapter identifies how current challenges and global context provide an agenda and opportunities for the renewal of primary health care and primary care, allied to the movement to achieve universal health coverage.

PRIMARY CARE AND PRIMARY HEALTH CARE

The term *primary care* has been used in many different ways: to describe a level of care or the setting of the health system, a set of treatment and prevention activities carried out by specific personnel, a set of attributes for the way care is delivered, or an approach to organizing health systems that is synonymous with the term *primary health care*. In 1996, the U.S. Institute of Medicine encompassed many of these different usages, defining primary care as "the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community."[1] We use this definition of *primary care* in this chapter. Primary care performs an essential function for health systems, providing the first point of contact when people seek health care, dealing with most problems, and referring patients onward to other services when necessary. As is increasingly evident in countries of all income levels, without strong primary care, health systems cannot function properly or address the health challenges of the communities they serve.

Primary care is only one part of a primary health care approach. The Declaration of Alma Ata, drafted in 1978 at the International Conference on Primary Health Care in Alma Ata (now Almaty in Kazakhstan), identified many features of primary care as being essential to achieving the goal of "health for all by the year 2000." However, it also identified the need to work across different sectors, address the social and economic factors that determine health, mobilize the participation of communities in health systems, and ensure the use and development of technology that was appropriate in terms of setting and cost. The declaration drew from the experiences of low- and middle-income countries in trying to improve the health of their people following independence. Commonly, these countries had built hospital-based systems similar to those in high-income countries. This effort had resulted in the development of high-technology services in urban areas while leaving the bulk of the population without access to health care unless they traveled great distances to these urban facilities. Furthermore, much of the population lacked access to basic public health measures. Primary health care efforts aimed to move care closer to where people lived, to ensure their involvement in decisions about their own health care, and to address key aspects of the physical and social environment essential to health, such as water, sanitation, and education.

After the Declaration of Alma Ata, many countries implemented reforms of their health systems based on primary health care. Most progress involved strengthening of primary care services; unexpectedly, however, much of this progress was seen in high-income countries, most of which constructed systems that made primary care available at low or no cost to their entire populations and that delivered the bulk of services in primary care settings. This endeavor also saw the reinforcement of family medicine as a specialty to provide primary care services. Even in the United States (an obvious exception to this trend), it became clear that the populations of states with more primary care physicians and services were healthier than those with fewer such resources.

[1]Institute of Medicine. Primary Care: America's Health in a New Era (1996).

Progress was also made in many low- and middle-income countries. However, the target of "health for all by the year 2000" was missed by a large margin. The reasons were complex but partly entailed a general failure to implement all aspects of the primary health care approach, particularly work across sectors to address social and economic factors that affect health and provision of sufficient human and other resources in order to make possible the access to primary care attained in high-income countries. Furthermore, despite the consensus in Alma Ata in 1978, the global health community rapidly became fractured in its commitment to the far-reaching measures called for by the declaration. Economic recession tempered enthusiasm for primary health care, and momentum shifted to programs concentrating on a few priority measures such as immunization, oral rehydration, breastfeeding, and growth monitoring for child survival. Success with these initiatives supported the continued movement of health development efforts away from the comprehensive approach of primary health care and toward programs that targeted specific public health priorities. This approach was reinforced by the need to address the HIV/AIDS epidemic. By the 1990s, primary health care had fallen out of favor in many global-health policy circles, and low- and middle-income countries were being encouraged to reduce public sector spending on health and to focus on cost-effectiveness analysis to provide a package of health care measures thought to offer the greatest health benefits.

HEALTH CHALLENGES IN LOW- AND MIDDLE-INCOME COUNTRIES

Low- and middle-income countries, defined by a per capita gross national income of <$12,476 (U.S.) per person per year, account for >80% of the world's population. Average life expectancy in these countries lags far behind that in high-income countries: whereas the average life expectancy at birth for a girl in high-income countries is 76 years, it is only 63 years for a girl in low-income countries. This discrepancy has received growing attention over the past 40 years. Initially, the situation in poor countries was characterized primarily in terms of high fertility and high infant, child, and maternal mortality rates, with most deaths and illnesses attributable to infectious or tropical diseases among remote, largely rural populations. With growing adult (and especially elderly) populations and changing lifestyles linked to global forces of urbanization, a new set of health challenges characterized by chronic diseases, environmental overcrowding, and road traffic injuries has emerged rapidly **(Fig. 462-1)**. The majority of tobacco-related deaths globally now occur in low- and middle-income countries, and the risk of a child's dying from a road traffic injury in Africa is more than twice that in Europe. Thus, low- and middle-income countries in the twenty-first century face a full spectrum of health challenges—infectious, chronic, and injury-related—at much higher incidences and prevalences than are documented in high-income countries and with many fewer resources to address these challenges.

Addressing these challenges, however, does not mean simply waiting for economic growth. Analysis of the association between wealth and health across countries reveals that, for any given level of wealth, there is a substantial variation in life expectancy at birth that has persisted despite overall global progress in life expectancy during the past 30 years **(Fig. 462-2)**. Health status in low- and middle-income countries varies enormously. Nations such as Cuba and Costa Rica have life expectancies and childhood mortality rates similar to or even better than those in high-income countries; in contrast, countries in sub-Saharan Africa and the former Soviet bloc have at times experienced significant reverses in these health markers in recent decades, particularly in the 1990s.

As Angus Deaton stated in the World Institute for Development Economics Research annual lecture on September 29, 2006, "People in poor countries are sick not primarily because they are poor but because of other social organizational failures, including health delivery, which are not automatically ameliorated by higher income." This analysis concurs with classic studies of the array of societal factors explaining good health in poor settings such as Cuba and Kerala

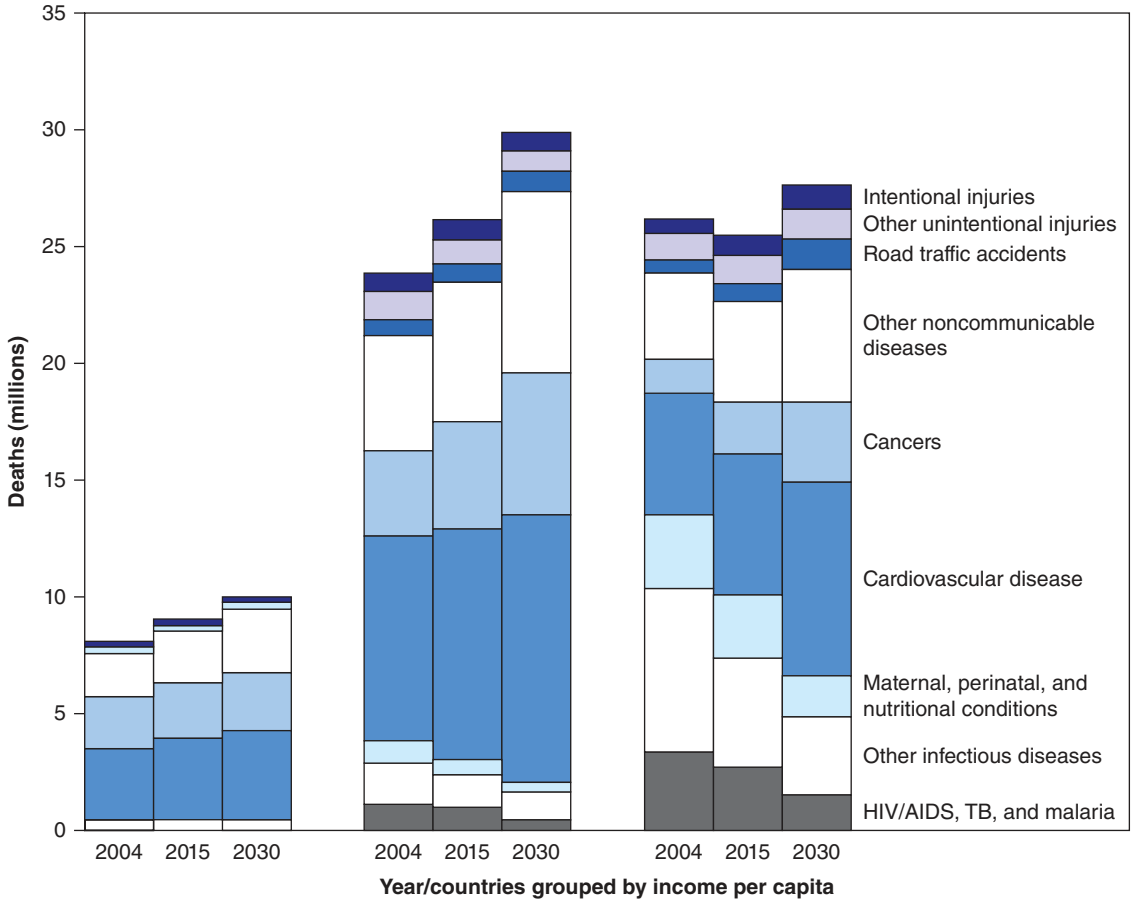

FIGURE 462-1 Projections of disease burden to 2030 for high-, middle-, and low-income countries (*left*, *center*, and *right*, respectively). TB, tuberculosis. *(Source: World Health Organization: The Global Burden of Disease 2004 Update, 2008.)*

State in India in the 1980s. Analyses conducted over the past three decades indeed show that rapid health improvement is possible in very different contexts. That some countries continue to lag far behind can be understood through a comparison of regional differences in progress in terms of life expectancy over this period **(Fig. 462-3)**.

As average levels of health vary across regions and countries, so too do they vary within countries **(Fig. 462-4)**. Indeed, disparities within countries are often greater than those between high-income and low-income countries. For example, if low- and middle-income countries could reduce their overall childhood mortality rate to that of the richest one-fifth of their populations, global childhood mortality could be decreased by 40%. Disparities in health are mostly a result of social and economic factors such as daily living conditions, access to resources, and ability to participate in life-affecting decisions. In most countries, the health care sector actually tends to exacerbate health inequalities (the "inverse-care law"); because of neglect and discrimination, poor and marginalized communities are much less likely to benefit from public health services than those that are better off. Reforming health systems toward people-centered primary care provides an opportunity to reverse these negative trends.

Health services have failed to make their contribution to reducing these pervasive social inequalities by ensuring universal access to existing, scientifically validated, low-cost interventions such as insecticide-treated bed nets for malaria, taxes on cigarettes, short-course chemotherapy for tuberculosis, antibiotic treatment for pneumonia, dietary modification and secondary prevention measures for high blood pressure and high cholesterol levels, and water treatment and oral rehydration therapy for diarrhea. Despite decades of "essential packages" and "basic" health campaigns, the effective implementation of what is already known to work appears (deceptively) to be difficult.

Recent analyses have begun to focus on "the how" (as opposed to "the what") of health care delivery, exploring why health progress is

slow and sluggish despite the abundant availability of proven interventions for health conditions in low- and middle-income countries. Three general categories of reasons are being identified: (1) shortfalls in performance of health systems; (2) stratifying social conditions; and (3) skews in science.

SHORTFALLS IN PERFORMANCE OF HEALTH SYSTEMS

Specific health problems often require the development of specific health interventions (e.g., tuberculosis requires short-course chemotherapy). However, the delivery of different interventions is often facilitated by a common set of resources or functions: money or financing, trained health workers, and facilities with reliable supplies fit for multiple purposes. Unfortunately, health systems in most low- and middle-income countries are largely dysfunctional at present.

In the large majority of low- and middle-income countries, the level of public financing for health is woefully insufficient: whereas high-income countries spend, on average, 7% of the gross domestic product on health, middle-income countries spend <4%, and low-income countries <3%. External financing for health through various donor channels grew rapidly in the first decade of the twenty-first century but has grown more slowly in the second decade to its current level of $37 billion. While these funds for health are significant, they represent <2% of total health expenditures in low- and middle-income countries and therefore are neither a sufficient nor a long-term solution to chronic underfinancing. In Africa, 70% of health expenditures come from domestic sources. The predominant form of health care financing—charging patients at the point of service—is the least efficient and the most inequitable, tipping millions of households into poverty annually.

Health workers, who represent another critical resource, are often inadequately trained and supported in their work. Recent estimates indicate a shortage of >7 million health workers, constituting a crisis that is greatly exacerbated by the migration of health workers from low- and middle-income countries to high-income countries. Sub-Saharan Africa carries 24% of the global disease burden but has only 3% of the health workforce **(Fig. 462-5)**. The International Organization for Migration estimated in 2006 that there were more Ethiopian physicians practicing in Chicago than in Ethiopia itself.

Critical diagnostics and drugs often do not reach patients in need because of supply-chain failures. Moreover, facilities fail to provide safe care: new evidence suggests much higher rates of adverse events among hospitalized patients in low- and middle-income countries than in high-income countries. Weak government planning, regulatory, monitoring, and evaluation capacities are associated with rampant, unregulated commercialization of health services and chaotic fragmentation of these services as donors "push" their respective priority programs. With such fragile foundations, it is not surprising that low-cost, affordable, validated interventions are not reaching those who need them.

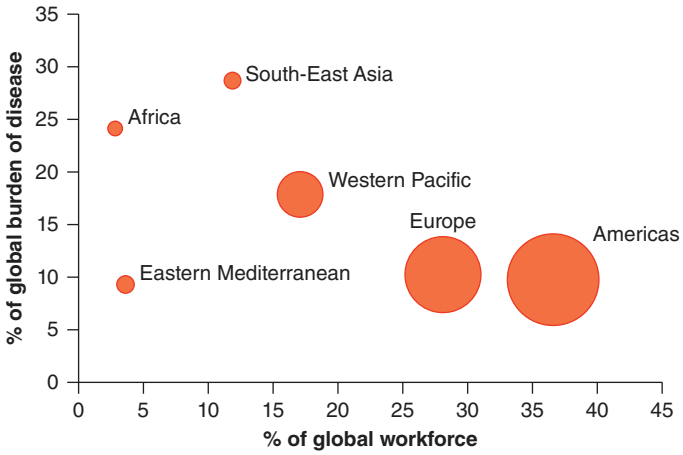

FIGURE 462-5 Global burden of disease and health workforce. *(Source: World Health Organization: Working Together for Health, 2006.)*

STRATIFYING SOCIAL CONDITIONS

Health care delivery systems do not exist in a vacuum but rather are embedded in a complex of social and economic forces that often stratify opportunities for health unfairly. Most worrisome are the pervasive forces of social inequality that serve to marginalize populations with disproportionately large health needs (e.g., the urban poor; illiterate mothers). Why should a poor slum dweller with no income be expected to come up with the money for a bus fare needed to travel to a clinic to learn the results of a sputum test for tuberculosis? How can a mother living in a remote rural village and caring for an infant with febrile convulsions find the means to get her child to appropriate care? Shaky or nonexistent social security systems, dangerous work environments, isolated communities with little or no infrastructure, and systematic discrimination against minorities are among the myriad forces with which efforts for more equitable health care delivery must contend.

SKEWS IN SCIENCE

While science has yielded enormous breakthroughs in health in high-income countries, with some spillover to low- and middle-income countries, many important health problems continue to affect primarily low- and middle-income countries whose research and development investments are deplorably inadequate. The past decade has seen growing efforts to right this imbalance with research and development investment for new drugs, vaccines, and diagnostics that effectively cater to the specific health needs of populations in low- and middle-income countries. For example, the Medicines for Malaria Venture has revitalized a previously "dry" pipeline for new malaria drugs. This is but one of many such efforts, but much more needs to be done.

As discussed above, the primary constraint on better health in low- and middle-income countries is related less to the availability of health technologies and more to their effective delivery. Underlying these systems and social challenges to greater equity in health is a major bias regarding what constitutes legitimate "science" to improve health equity. The lion's share of health research financing is channeled toward the development of new technologies—drugs, vaccines, and diagnostics; in contrast, virtually no resources are directed toward research on how health care delivery systems can become more reliable and overcome adverse social conditions. The complexity of systems and social context is such that this issue of delivery requires an enormous investment in terms not only of money but also of scientific rigor, with the development of new research methods and measures and the attainment of greater legitimacy in the mainstream scientific establishment.

These common challenges to low- and middle-income countries partly explain the resurgence of interest in the primary health care approach and the emergence of a global movement toward universal health coverage, now enshrined as one of the Sustainable Development Goal targets adopted in Agenda 2030 by all countries at the United Nations in September 2015. In some countries (mostly middle-income), significant progress has been made in expanding coverage by health systems based on primary care and even in improving indicators of population health. More countries are embarking on the creation of primary care services despite the challenges that exist, particularly in low-income countries. Even when these challenges are acknowledged, there are many reasons for optimism that low- and middle-income countries can accelerate progress in building primary care as a key vehicle toward achieving universal health coverage.

PRIMARY HEALTH CARE IN THE TWENTY-FIRST CENTURY

The new millennium has seen a resurgence of interest in primary health care as a means of addressing global health challenges. This interest has been driven by many of the same issues that led to the Declaration of Alma Ata: rapidly increasing disparities in health between and within countries, spiraling costs of health care at a time when many people lack quality care, dissatisfaction of communities with the care they are able to access, and failure to address changes in health threats, especially noncommunicable disease epidemics. These challenges require a comprehensive approach and strong health systems with effective primary care. Global health development agencies have recognized that sustaining gains in public health priorities such as HIV/AIDS requires not only robust health systems but also the tackling of social and economic factors related to disease incidence and progression. Weak health systems have proved a major obstacle to delivering new technologies, such as antiretroviral therapy, to all who need them. Changing disease patterns have led to a demand for health systems that can treat people as individuals whether or not they present to a health facility with the public health "priority" (e.g., HIV/AIDS or tuberculosis) to which that facility is targeted. We discuss experiences in low- and middle-income countries in relation to primary care in greater detail below. First, we consider the features of primary health care and primary care as currently understood.

REVITALIZATION OF PRIMARY HEALTH CARE

At the 2009 World Health Assembly (an annual meeting of all countries to discuss the work of the World Health Organization [WHO]), a resolution was passed reaffirming the principles of the Declaration of Alma Ata and the need for national health systems to be based on primary health care. This resolution did not suggest that nothing had changed in the intervening 30 years since the declaration, nor did it dispute that its prescription needed reframing in light of changing public health needs. The 2008 WHO World Health Report describes how a primary health care approach is necessary "now more than ever" to address global health priorities, especially in terms of disparities and new health challenges. As discussed below, this report highlights four broad areas in which reform is required **(Fig. 462-6)**. One of these areas—the need to organize health care so that it places the needs of people first—essentially relates to the necessity for strong primary care in health systems and what this requirement entails. The other three areas also relate to primary care. All four areas require action to move health systems in a direction that will reduce disparities and increase the satisfaction of those they serve. The World Health Report's recommendations present a vision of primary health care that is based on the principles of Alma Ata, but that differs from many attempts to implement primary health care in the 1970s and 1980s.

Universal Coverage Reforms to Improve Health Equity Despite progress in many countries, most people in the world can receive health care services only if they can pay at the point of service. Disparities in health are caused not only by a lack of access

FIGURE 462-6 The four reforms of primary health care renewal. *(Source: World Health Organization: Primary Health Care: Now More Than Ever. World Health Report 2008.)*

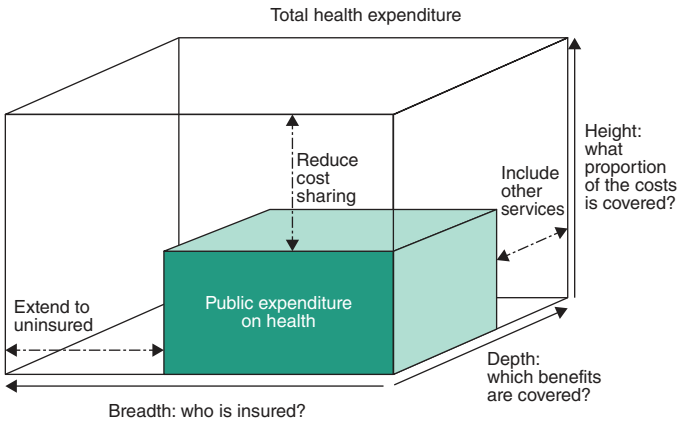

FIGURE 462-7 Three ways of moving toward universal coverage.

to necessary health services but also by the impact of expenditure on health. More than 100 million people are driven into poverty each year by health care costs, with countless others deterred from accessing services at all. Moving toward prepayment financing systems for universal coverage, which ensure access to a comprehensive package of services according to need without precipitating economic ruin, has therefore emerged as a major priority in low- and middle-income countries. Increasing coverage of health services can be considered in terms of three axes: the proportion of the population covered, the range of services underwritten, and the percentage of costs paid (Fig. 462-7). Moving toward universal health coverage requires ensuring the availability of health care services to all, eliminating barriers to access, and organizing pooled financing mechanisms, such as taxation or insurance, to remove user fees at the point of service. It also requires measures beyond financing, including expansion of health services in poorly served areas, improvement in the quality of services provided to marginalized communities, and increased coverage of other social services that significantly affect health (e.g., education).

Service Delivery Reforms to Make Health Systems People-Centered Health systems have often been organized around the needs of those who provide health care services, such as clinicians and policy makers. The result is a centralization of services or the provision of vertical programs that target single diseases. The principles of primary health care, including the development of primary care, reorient care around the needs of the people to whom services cater. This "people-centered" approach aims to provide health care that is both more effective and appropriate.

The increase in noncommunicable diseases in low- and middle-income countries offers a further stimulus for urgent reform of service delivery to improve chronic disease care. As discussed above, large numbers of people currently fail to receive relatively low-cost interventions that have reduced the incidence of these diseases in high-income countries. Delivery of these interventions requires health systems that can address multiple problems and manage people over a long period within their own communities, yet many low- and middle-income countries are only now starting to adapt and build primary care services that can address noncommunicable diseases and communicable diseases requiring chronic care. Even some countries (e.g., Iran) that have had significant success in reducing communicable diseases and improving child survival have been slow to adapt their health systems to rapidly accelerating noncommunicable disease epidemics.

People-centered care requires a safe, comprehensive, and integrated response to the needs of those presenting to health systems, with treatment at the first point of contact or referral to appropriate services. Because no discrete boundary separates people's needs for health promotion, curative interventions, and rehabilitation services across different diseases, primary care services must address all presenting problems in a unified way. Meeting people's needs also involves improved communication between patients and their clinicians, who must take the time to understand the impact of the patients' social context on the problems they present with. This enhanced understanding is made possible by improvements in the continuity of care so that responsibility transcends the limited time people spend in health care facilities. Primary care plays a vital role in navigating people through the health system; when people are referred elsewhere for services, primary care providers must monitor the resulting consultations and perform follow-up. All too often, people do not receive the benefit of complex interventions undertaken in hospitals because they lose contact with the health care system once discharged. Comprehensiveness and continuity of care are best achieved by ensuring that people have an ongoing personal relationship with a care team.

Public Policy Reforms to Promote and Protect the Health of Communities Public policies in sectors other than health care are essential to reduce disparities in health and to make progress toward global public health targets. The 2008 final report of the WHO Commission on Social Determinants of Health provides an exhaustive review of the multisectoral policies required to address health inequities at the local, national, and global levels. Advances against major challenges such as HIV/AIDS, tuberculosis, emerging pandemics, cardiovascular disease, cancers, and injuries require effective collaboration with sectors such as transport, housing, labor, agriculture, urban planning, trade, and energy. While tobacco control provides a striking example of what is possible if different sectors work together toward health goals, the lack of implementation of many evidence-based tobacco control measures in most countries just as clearly illustrates the difficulties encountered in such multisectoral work and the unrealized potential of public policies to improve health. At the local level, primary care services can help enact health-promoting public policies in other sectors.

Leadership Reforms to Make Health Authorities More Reliable The Declaration of Alma Ata emphasized the importance of participation by people in their own health care. In fact, participation is important at all levels of decision-making. Contemporary health challenges require new models of leadership that acknowledge the role of government in reducing disparities in health but that also recognize the many types of organizations that provide health care services. Governments need to guide and negotiate among these different groups, including nongovernmental organizations (NGOs) and the private sector, and to provide strong regulation where necessary. This difficult task requires a massive reinvestment in leadership and governance capacity, especially if action by different sectors is to be effectively implemented. Moreover, disadvantaged groups and other actors are increasingly expecting that their voices and health needs will be included in the decision-making process. The complex landscape for leadership at the national level is mirrored in many ways at the international or global level. The transnational character of health and the increasing interdependence of countries with respect to outbreak diseases, climate change, security, migration, and agriculture place a premium on more effective global health governance.

EXPERIENCES WITH PRIMARY CARE IN LOW- AND MIDDLE-INCOME COUNTRIES

Aspects of the primary health care approach described above, with an emphasis on primary care services, have been implemented to varying degrees in many low- and middle-income countries over the past half-century. As discussed above, some of these experiences inspired and informed the Declaration of Alma Ata, which itself led many more countries to attempt to implement primary health care. This section describes the experiences of a selection of low- and middle-income countries in improving primary care services that have enhanced the health of their populations.

Before Alma Ata, few countries had attempted to develop primary care on a national level. Rather, most focused on expanding primary care services to specific communities (often rural villages), making use of community volunteers to compensate for the absence of facility-based care. In contrast, in the post–World War II period, China invested in primary care on a national scale, and life expectancy doubled within roughly 20 years. The Chinese expansion of primary care

services included a massive investment in infrastructure for public health (e.g., water and sanitation systems) linked to innovative use of community health workers. These "barefoot doctors" lived in and expanded care to rural villages. They received a basic level of training that enabled them to provide immunizations, maternal care, and basic medical interventions, including the use of antibiotics. Through the work of the barefoot doctors, China brought low-cost universal basic health care coverage to its entire population, most of which had previously had no access to these services.

In 1982, the Rockefeller Foundation convened a conference to review the experiences of China along with those of Costa Rica, Sri Lanka, and the state of Kerala in India. In all of these locations, good health care at low cost appeared to have been achieved. Despite lower levels of economic development and health spending, all of these jurisdictions, along with Cuba, had health indicators approaching—or in some cases exceeding—those of developed countries. Analysis of these experiences revealed a common emphasis on primary care services, with expansion of care to the entire population free of charge or at low cost, combined with community participation in decision-making about health services and coordinated work in different sectors (especially education) toward health goals. During the more than three decades since the Rockefeller meeting, some of these countries have built on this progress, while others have experienced setbacks. Recent experiences in developing primary care services show that the same combination of features is necessary for success. For example, Brazil—a large country with a dispersed population—has made major strides in increasing the availability of health care in the past quarter century. In this millennium, the Brazilian Family Health Program has expanded progressively across the country, with almost all areas now covered. This program provides communities with free access to primary care teams made up of primary care physicians, community health workers, nurses, dentists, obstetricians, and pediatricians. These teams are responsible for the provision of primary care to all people in a specified geographic area—not only those who access health clinics. Moreover, individual community health workers are responsible for a named list of people within the area covered by the primary care team. Problems with access to health care persist in Brazil, especially in isolated areas and urban slums. However, solid evidence indicates that the Family Health Program has already contributed to impressive gains in population health, particularly in terms of childhood mortality and health inequities. In fact, this program has already had an especially marked impact on childhood mortality reduction in less developed areas **(Fig. 462-8)**.

Chile has also built on its existing primary care services in the past decade, aiming to improve the quality of care and the extent of coverage in remote areas, above all for disadvantaged populations. This effort has been made in concert with measures aimed at reducing social inequalities and fostering development, including social welfare benefits for families and disadvantaged groups and increased access to early-childhood educational facilities. As in Brazil, these steps have improved maternal and child health and have reduced health inequities. In addition to directly enhancing primary care services, Brazil and Chile have instituted measures to increase both the accountability of health providers and the participation of communities in decision-making. In Brazil, national and regional health assemblies with high levels of public participation are integral parts of the health policy-making process. Chile has instituted a patient's charter that explicitly specifies the rights of patients in terms of the range of services to which they are entitled.

Other countries that have made recent progress with primary health care include Bangladesh, once one of the poorest countries in the world and still relatively poor. Since achieving its independence from Pakistan in 1971, Bangladesh has seen a dramatic increase in life expectancy, and childhood mortality rates are now lower than those in neighboring nations such as India and Pakistan. The expansion of access to primary care services has played a major role in these achievements. This progress has been spearheaded by a vibrant NGO community that has focused its attention on improving the lives and livelihoods of poor women and their families through innovative and integrated microcredit, education, and primary care programs.

The above examples, along with others from the past 30 years in countries such as Thailand, Malaysia, Portugal, and Oman, illustrate how the implementation of a primary health care approach, with a greater emphasis on primary care, has led to better access to health care services—a trend that has not been seen in many other low- and middle-income countries. This trend, in turn, has contributed to improvements in population health and reductions in health inequities. However, as these nations have progressed, other countries have shown how previous gains in primary care can easily be eroded. In sub-Saharan Africa, undermining of primary care services contributed to catastrophic reversals in health outcomes catalyzed by the HIV/AIDS epidemic. Countries such as Botswana and Zimbabwe implemented primary health care strategies in the 1980s, increasing access to care and making impressive gains in child health. Both countries were severely affected by HIV/AIDS, with pronounced decreases in life expectancy. However, Zimbabwe has also seen political turmoil, a decline of health and other social services, and the flight of health personnel, whereas Botswana has maintained primary care services to a greater extent and has managed to organize widespread access to antiretroviral therapy for people living with HIV/AIDS. Zimbabwe's health situation has therefore become more desperate than that in Botswana.

China provides a particularly striking example of how changes in health policy relevant to the organization of health systems **(Fig. 462-9)** can have rapid, far-reaching consequences for population health. Even as the 1982 Rockefeller conference was celebrating China's achievements in primary care, its health system was unraveling. The decision to open up the economy in the early 1980s led to rapid privatization of the health sector and the breakdown of universal health coverage. As a result, by the end of the 1980s, most people, especially the poorer segments of the population, were paying directly out of pocket for health care, and almost no Chinese had insurance—a dramatic transformation. The "barefoot doctor" schemes collapsed, and the population either turned to care paid for at hospitals or simply became unable to access care. This undermining of access to primary care services in the Chinese system and the resulting increase in impoverishment due to illness contributed to the stagnation of progress in health in China at the same time that incomes in that country increased at an unprecedented rate. Reversals in primary care have meant that China now increasingly faces health care issues similar to those faced by India, although the country has more recently implemented measures to restore universal health coverage, with significant success. In both countries, rapid economic growth has been linked to lifestyle changes and noncommunicable disease epidemics. The health care systems of the two nations share

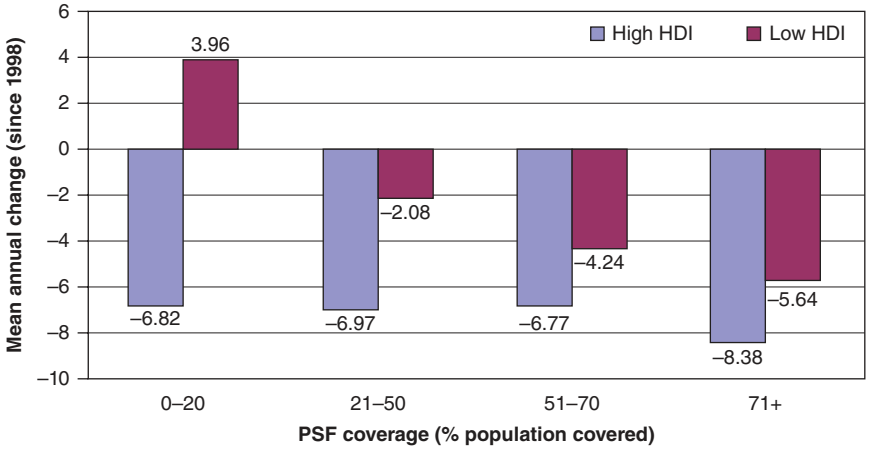

FIGURE 462-8 Improvements in childhood mortality following the Family Health Program in Brazil. HDI, Human Development Index; PSF, Program Saúde da Família (Family Health Program). *(Source: Ministry of Health, Brazil.)*

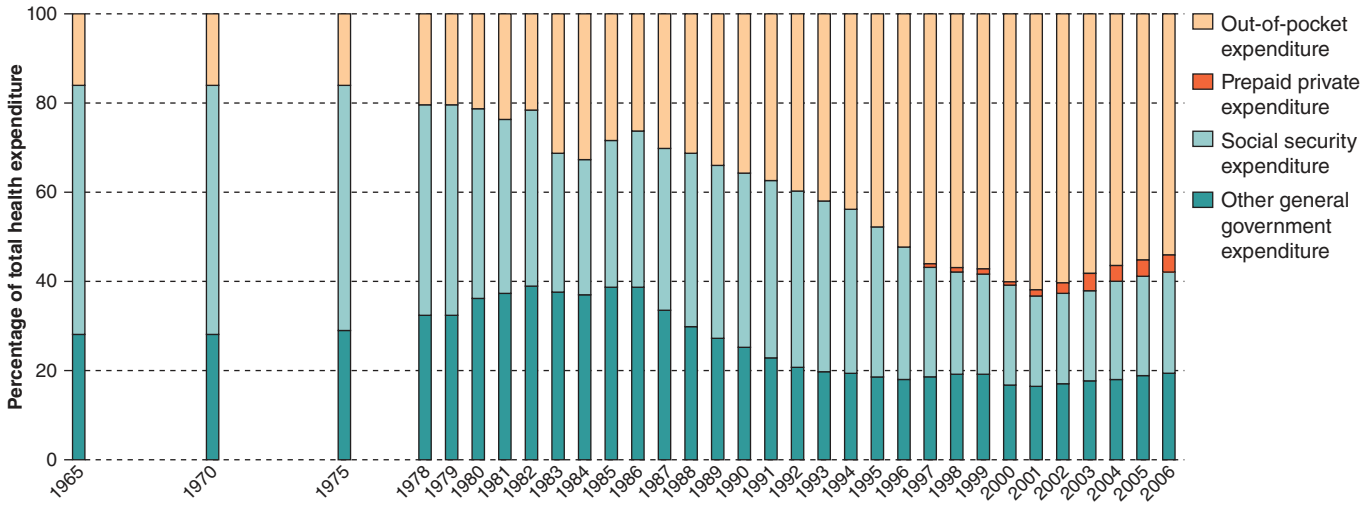

FIGURE 462-9 Changes in source of health expenditure in China over the past 40 years. *(Source: World Health Organization: Primary Health Care: Now More Than Ever. World Health Report 2008.)*

two negative features that are common when primary care is weak: a disproportionate focus on specialty services provided in hospitals and unregulated commercialization of health services. China and India have both seen expansion of private hospital services that cater to middle-class and urban populations who can afford care; at the same time, hundreds of millions of people in rural areas now struggle to access the most basic services. Even in the former groups, a lack of primary care services has been associated with late presentation with illness and with insufficient investment in primary prevention approaches. This neglect of prevention poses a risk of large-scale epidemics of cardiovascular disease, which could endanger continued economic growth. In addition, the health systems of both countries now depend for the majority of their funding on out-of-pocket payments by people when they use services. Thus substantial proportions of the population must sacrifice other essential goods as a result of health expenditure and may even be driven into poverty by this cost. The commercial nature of health services with inadequate or no regulation has also led to the proliferation of charlatan providers, inappropriate care, and pressure for people to pay for expensive and sometimes unnecessary care. Commercial providers have limited incentives to use interventions (including public health measures) that cannot be charged for or that are what the person who is paying can afford.

Faced with these problems, China and India have implemented measures to strengthen primary health care. China has increased government funding of health care, has taken steps toward restoring health insurance, and has enacted a target of universal access to primary care services. India has similarly mobilized funding to greatly expand primary care services in rural areas and is now duplicating this process in urban settings. Both countries are increasingly using public resources from their growing economies to fund primary care services.

These encouraging trends are illustrative of new opportunities to implement a primary health care approach and strengthen primary care services in low- and middle-income countries. Brazil, India, China, and Chile are being joined by many other low- and middle-income countries, including Indonesia, Mexico, the Philippines, Turkey, Rwanda, Ethiopia, South Africa, and Ghana, in ambitious initiatives mobilizing new resources to move toward universal health coverage—the provision of quality health services in a timely manner at affordable cost.

OPPORTUNITIES TO BUILD PRIMARY CARE IN LOW- AND MIDDLE-INCOME COUNTRIES

Global public health targets will not be met unless health systems are significantly strengthened. More money is currently being spent on health than ever before. In 2013, global health spending totaled $7.8 trillion (U.S.)—more than double the amount spent a decade earlier. Although most expenditure occurs in high-income countries, spending in many emerging middle-income countries has rapidly accelerated, as has the allocation of monies for this purpose by both governments in and donors to low-income countries. These twin trends—greater emphasis on building health systems based on primary care and allotment of more money for health care—provide opportunities to address many of the challenges discussed above in low- and middle-income countries.

Accelerating progress requires a better understanding of how global health initiatives can more effectively facilitate the development of primary care in low-income countries. A review by the WHO Maximizing Positive Synergies Collaborative Group looked at programs funded by the Global Fund to Fight AIDS, Tuberculosis and Malaria; the Global Alliance for Vaccines and Immunisation (GAVI); the U.S. President's Emergency Plan for AIDS Relief (PEPFAR); and the World Bank (HIV/AIDS). This group found that global health initiatives had improved access to and quality of the targeted health services and had led to better information systems and more adequate financing. The review also identified the need for better alignment of global health initiatives with other national health priorities and systematic exploitation of potential synergies. If global health initiatives implement programs that work in tandem with other components of national health systems without undermining staffing and procurement of supplies, they have the potential to contribute substantially to the capacity of health systems to provide comprehensive primary care services.

Even in the aftermath of the global financial crisis, global health initiatives continued to draw significant funding. In 2009, for example, U.S. President Barack Obama announced increasing development assistance from the United States for global health, earmarking $63 billion over the period 2009–2014 for a Global Health Initiative. New funding is also promised through a range of other initiatives focusing particularly on maternal and child health in low-income countries. The general trend is to coordinate this funding in order to reduce fragmentation of national health systems and to concentrate more on strengthening these systems. Comprehensive primary care in low-income countries must inevitably deal with the rapid emergence of chronic diseases and the growing prominence of injury-related health problems; thus international health development assistance must become more responsive to these needs. More recent political currents that threaten global health funding from traditional sources only underscore the need to take a more comprehensive and integrated health systems approach to the use of these funds.

Beyond funding for health services, other opportunities exist. Increased social participation in health systems can help build primary care services. In many countries, political pressure from community advocates for more holistic and accountable care as well as entrepreneurial initiatives to scale up community-based services through

NGOs have accelerated progress in primary care without major increases in funding. Participation of the population in the provision of health care services and in relevant decision-making often drives services to cater to people's needs as a whole rather than to narrow public health priorities.

Participation and innovation can help address critical issues related to the health workforce in low- and middle-income countries by establishing effective people-centered primary care services. Many primary care services do not need to be delivered by a physician or a nurse. Multidisciplinary teams can include paid community workers who have access to a physician if necessary but who can provide a range of health services on their own. In Ethiopia, more than 38,000 community health workers have been trained and deployed to improve access to primary care services, and there is increasing evidence that this measure is contributing to better health outcomes. In India, more than 600,000 community health advocates have been recruited as part of expanded rural primary care services. In Niger, the deployment of community health workers to deliver essential child health interventions (as a component of integrated community case management) has had impressive results in reducing childhood mortality and decreasing disparities. After the Declaration of Alma Ata, experiences with community health workers were mixed, with particular problems about levels of training and lack of payment. Current endeavors are not immune from these concerns. However, with access to physician support and the deployment of teams, some of these concerns may be addressed. Growing evidence from many countries indicates that shifting appropriate tasks to primary care workers who have had shorter, less expensive training than physicians will be essential to address the human resources crisis.

Finally, recent improvements in information and communication technologies, particularly mobile phone and internet systems, have created the potential for systematic implementation of e-health, telemedicine, and improved health data initiatives in low- and middle-income countries. These developments raise the tantalizing possibility that health systems in these countries, which have long lagged behind those in high-income countries but are less encumbered by legacy systems that have proved hard to modernize in many settings, could leapfrog their wealthier counterparts in exploiting these technologies. Although the challenges posed by poor or absent infrastructure and investment in many low- and middle-income countries cannot be underestimated and will need to be addressed to make this possibility a reality, the rapid rollout of mobile networks and their use for health and other social services in many low-income countries where access to fixed telephone lines was previously very limited offer great promise in building primary care services in low- and middle-income countries.

CONCLUSION

As concern continues to mount about glaring inequities in global health, there is a growing commitment to redress these egregious shortfalls, as exemplified by the central place of equity in the United Nations' Sustainable Development Goals adopted in 2015, including a specific target on the achievement of universal health coverage in all countries by 2030. This commitment begins first and foremost with a clear vision of the fundamental importance of health in all countries, regardless of income. The values of health and health equity are shared across all borders, and primary health care provides a framework for their effective translation across all contexts.

The translation of these fundamental values has its roots in four types of reform that reflect the distinct but interlinked challenges of (re)orienting a society's resources on the basis of its citizens' health needs: (1) organizing health care services around the needs of people and communities; (2) harnessing services and sectors beyond health care to promote and protect health more effectively; (3) establishing sustainable and equitable financing mechanisms for universal health coverage; and (4) investing in effective leadership of the whole of society. This common primary health care agenda highlights the striking similarity, despite enormous differences in context, in the nature and direction of the reforms that national health systems must undertake to promote greater equity in health. This shared agenda is complemented by the growing reality of global health interconnectedness due, for example, to shared microbial threats, bridging of ethnolinguistic diversity, flows in migrant health workers, and mobilization of global funds to support the neediest populations. Embracing solidarity in global health while strengthening health systems through a primary health care approach is fundamental to sustained progress in global health.

463 The Biology of Aging

Rafael de Cabo, David G. Le Couteur

THE IMPACT OF AGING ON MEDICINE

Aging and old age are among the most significant challenges facing medicine this century. The aging process is the major risk factor underlying disease and disability in developed nations, while older people respond differently to therapies developed for younger adults (usually with less effectiveness and more adverse reactions). Modern medicine and healthier lifestyles have increased the likelihood that younger adults will now achieve old age. However, this has led to rapidly increasing numbers of older people, often encumbered with age-related disorders that are predicted to overwhelm health care systems. Improved health in old age and further extension of human health span are now likely to be generated primarily from increased understanding of the biology of aging, age-related susceptibility to disease, and modifiable factors that influence the aging process.

Definitions of Aging Aging is easy to recognize but difficult to define. Most definitions of aging indicate that it is a progressive process associated with declines in structure and function, impaired maintenance and repair systems, increased susceptibility to disease and death, and reduced reproductive capacity. There are both statistical and phenotypic components to aging. As recognized by Gompertz in the nineteenth century, aging in humans is associated with an exponential risk of mortality with time **(Fig. 463-1)**, although it is now realized that this plateaus in extreme old age because of healthy survivor bias. The phenotypic components of aging include structural and functional changes that are separated, somewhat artificially, into either primary aging changes (e.g., sarcopenia, grey hair, oxidative stress, increased peripheral vascular resistance) or age-related disease (e.g., dementia, osteoporosis, arthritis, insulin resistance, hypertension).

Definitions of aging rarely acknowledge the possibility that some of those biological and functional changes with aging might be adaptive or even reflect improvement and gain. Nor do they emphasize the impact of aging on responses to medical treatments. Old age is associated with increased vulnerability to many perturbations, including therapeutic interventions. This is a critical issue for clinicians—aging would be a less difficult problem if our disease-specific therapies retained their balance of risk to benefit into old age.

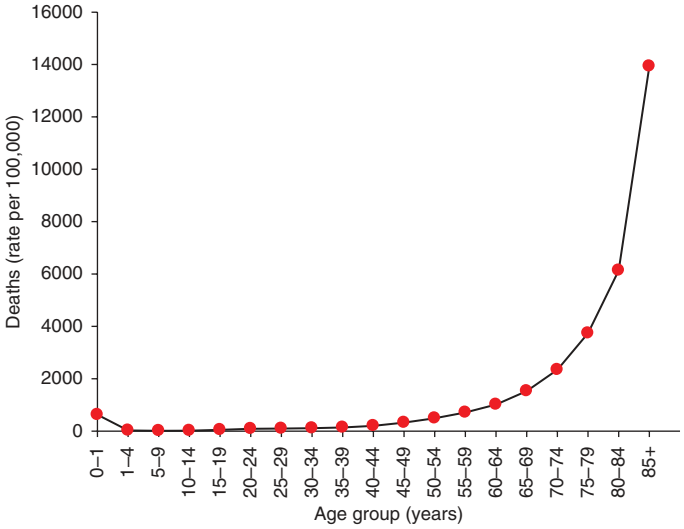

FIGURE 463-1 The rates of death in the United States (2010) showing exponential increase in mortality risk with chronological age.

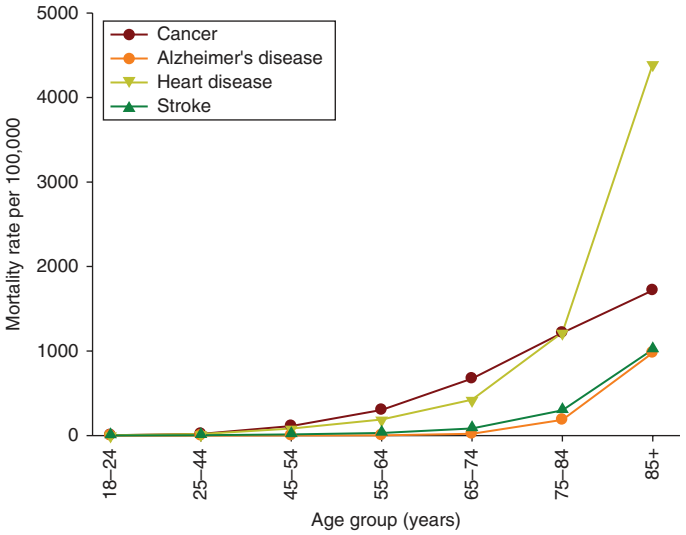

FIGURE 463-2 The rates of most common chronic diseases and related mortality increase with old age. *(Data from USA 2008-2010 CDC.)*

Aging and Disease Susceptibility Old age is the major independent risk factor for chronic diseases (and associated mortality) that are most prevalent in developed countries such as cardiovascular disease, cancers, and neurodegenerative disorders **(Fig. 463-2)**. Consequently, older people have multiple comorbidities, usually in the range of 5–10 illnesses per person.

Disease in older people is typically multifactorial with a strong component related to the underlying aging process. For example, in younger patients with dementia, Alzheimer's disease is a single disorder confirmed by examining brain tissue for plaques and tangles containing amyloid and tau proteins. However, the vast majority of people with dementia are elderly, and here the association between typical Alzheimer's neuropathology and dementia becomes less definitive. In the oldest-old, the prevalence of Alzheimer-type brain pathology is similar in people with and without clinical features of dementia. On the other hand, brains of older people with dementia usually show mixed pathology with evidence of Alzheimer's pathology along with features of other dementias such as vascular lesions, Lewy bodies, and non-Alzheimer's tauopathy. Many typical aging changes, such as microvascular dysfunction, oxidative injury, and mitochondrial impairment underlie many of the pathological changes.

The Longevity Dividend "Compression of morbidity" refers to the concept that the burden of lifetime illness might be compressed by medical interventions into a shorter period before death without necessarily increasing longevity. However, continuing development of successful therapeutic and preventive interventions focusing on individual diseases is less effective in older people because of multiple comorbidities, complications of overtreatment, and competing causes of death. Therefore, it has been proposed that further gains in health span and life expectancy will be achieved by a single intervention that delays aging and age-related disease susceptibility, rather than multiple treatments each targeting different individual age-related illnesses. This is called the "longevity dividend" and is driving an explosion of research into aging biology and, more importantly, interventions—genetic, pharmaceutical, and nutritional—that influence the rate of aging and delay age-related disease.

EVOLUTIONARY MECHANISMS FOR AGING

At the most basic level, living things have only two approaches to maintain their existence: immortality or reproduction. In a changing environment, reproduction combined with a finite life span has proved to be the successful strategy. Of course, finite life span is not the same as aging—although aging, by definition, contributes to a finite life span.

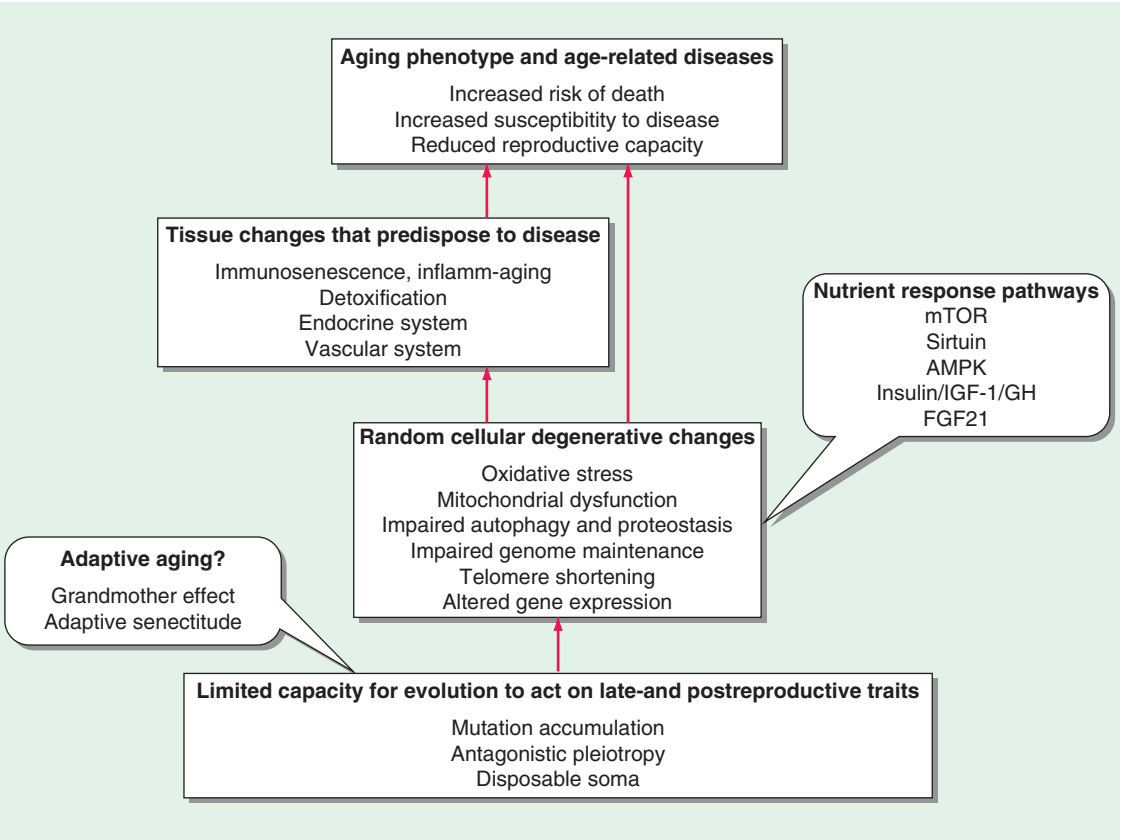

FIGURE 463-3 Schema linking evolution, cellular and tissue changes with aging. The call-out blue boxes indicate factors that might delay the aging process including nutrient response pathways and, possibly, adaptive evolutionary effects.

Many evolutionary theories related to aging are linked by their attempts to explain this interaction between reproduction and longevity **(Fig. 463-3)**. Most mainstream aging theories stem from the fact that evolution is driven by early reproductive success, whereas there is minimal selection pressure for late-life reproduction or postreproductive survival. Aging is seen as the random degeneration resulting from the inability of evolution to prevent it, i.e., the nonadaptive consequence of evolutionary "neglect." This conclusion is supported by studies that restricted reproduction to later life in the fruit fly, *Drosophila melanogaster*, thus permitting natural selection to operate on later life traits and leading to an increase in longevity. Likewise, many of the interventions that delay aging are associated with reduced reproductive capacity.

There are some species of plants and animals that do not appear to age, or at least they undergo an extremely slow aging process, termed "negligible senescence." The mortality rates of these species are relatively constant with time and they do not display any obvious phenotypic changes of aging. Conversely, some living things undergo programmed death immediately after reproduction such as annual plants and semelparous animals **(Fig. 463-4)**. However, many other living things from yeast to humans undergo a gradual aging process leading to death that is surprisingly similar at the cellular and biochemical level across taxa.

Some of the major classical evolutionary theories of aging include:

- *Programmed death*. The first evolutionary theory of aging was proposed by Weismann in 1882. This theory states that aging and death are programmed and have evolved to remove older animals from the population so that environmental resources such as food and water are freed up for younger members of the species.
- *Mutation accumulation*. This theory was proposed by Medawar in 1952. Natural selection is most powerful for those traits that influence reproduction in early life, and therefore, the ability of evolution to shape our biology declines with age. Germline mutations that are deleterious in later life can accumulate simply because natural selection cannot act to prevent them.
- *Antagonistic pleiotropy*. George C. Williams extended Medawar's theory when he proposed that evolution can allow for the selection of genes that are pleiotropic, i.e., beneficial for survival and reproduction in early life, but harmful in old age. For example, genes for sex hormones are necessary for reproduction in early life but contribute to the risk of cancer in old age.
- *Life history theory*. Evolution is influenced by the way that limited resources are allocated to all aspects of life including development, sexual maturation, reproduction, number of offspring, and senescence and death. Therefore "trade-offs" occur between these phases of life. For example, in a hostile environment, survival is highest

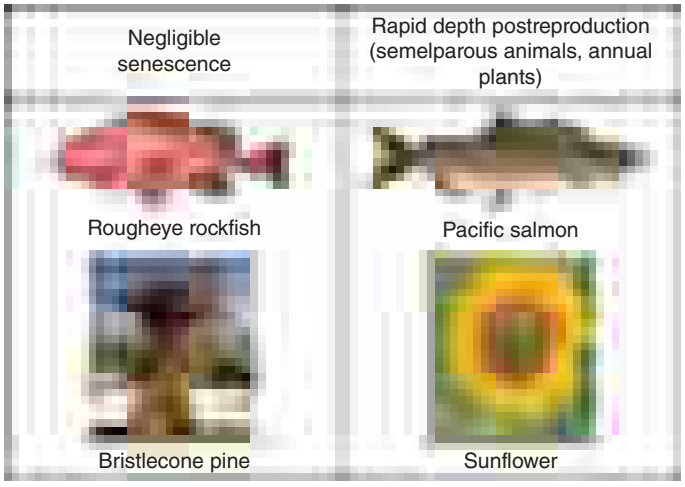

FIGURE 463-4 The typical features of aging (aging phenotype and exponential increase in risk of death) are not universal findings in living things. Some living things (e.g., Rockfish and the Bristlecone pine, sometimes called the Methuselah tree) undergo negligible senescence while others die almost immediately after first reproductive effort is completed (e.g., semelparous animals and annual plants).

for those species that have large numbers of offspring and short life span while in a safe and abundant environment, survival is highest for those species that invest resources in a smaller number of offspring and a longer life.

- *Disposable soma theory*. Kirkwood and Holliday in 1979 combined many of these ideas in the disposable soma theory of aging. There are finite resources available for the maintenance and repair of both germ and soma cells so there must be a trade-off between germ cells (i.e., reproduction) versus soma cells (i.e., longevity and aging). The soma cells are disposable from an evolutionary perspective, so they accumulate damage that causes aging while resources are preferentially diverted to the maintenance and repair of the germ cells. For example, the longevity of nematode worm, *Caenorhabditis elegans* is increased when its germ cells are ablated early in life.

All of these theories assume that natural selection has negligible or negative influences on aging. Some ideas propose that aspects of aging might be adaptive and raise the possibility that evolution can act on the aging process in a positive way. These include:

- *Grandmother hypothesis*. The grandmother hypothesis proposed by Hamilton in 1966 describes how evolution can enhance old age. In some animals, including humans, the survival of multiple, dependent offspring is beyond the capacity and resources of their mother. In this situation, the presence of a long-lived grandmother who shares in care of her grandchildren can have a major impact on their survival. These children share some of the genes of their grandmother including those that promoted their grandmother's longevity.
- *Mother's curse*. Mitochondrial dysfunction is a key component of the aging process. Mitochondria contain their own DNA and are only passed on from mother to child, because sperm cells contain almost no mitochondria. Therefore, natural selection can only act on the evolution of mitochondrial DNA in females. The "mother's curse" of the maternal inheritance of mitochondrial DNA might explain why females live longer and age more slowly than males.
- *Adaptive senectitude*. Many traits that are harmful in younger humans such as obesity, hypertension, oxidative stress, and declines in growth hormone and insulin-like growth factor type I (IGF-1) paradoxically appear to be associated with greater survival and function in old age. Perhaps driven by the grandmother effect, this might represent "adaptive senectitude" or "reverse antagonistic pleiotropy" whereby some traits that are harmful in young people become beneficial in older people.

CELLULAR PROCESSES THAT ACCOMPANY AGING

Many cellular processes change with aging. These are generally considered to be degenerative and stochastic or random changes that reflect some sort of time-dependent damage (Fig. 463-3) and have been called the hallmarks and pillars of aging. Whether any of these is the root cause of aging is unknown but they all contribute to the aging phenotype and disease susceptibility.

Oxidative Stress and the "Free Radical Theory of Aging" Free radicals are chemical species that are highly reactive because they contain unpaired electrons. Oxidants are oxygen-based free radicals that include the hydroxyl free radical, superoxide, and hydrogen peroxide. Most cellular oxidants are waste products generated by mitochondria during the production of ATP from oxygen. More recently, the role of oxidants in cellular signaling and inflammatory responses has been recognized. Unchecked, oxidants can generate chain reactions leading to widespread damage to biological molecules. Cells contain numerous antioxidant defense mechanisms to prevent such oxidative stress including enzymes (superoxide dismutase, catalase, glutathione peroxidase) and chemicals (uric acid, ascorbate). In 1956, Harman proposed the "free radical theory of aging" whereby oxidants generated by metabolism or irradiation are responsible for age-related damage. It is now well established that old age in most species is associated with increased oxidative stress, for example to DNA (8-hydroxyguanosine derivatives), proteins (carbonyls), lipids (lipoperoxides, malondialdehydes), and prostaglandins (isoprostanes). Conversely, many of the cellular antioxidant defense mechanisms including the antioxidant enzymes decline in old age. The free radical theory of aging has spawned numerous studies of supplementation with antioxidants such as vitamin E to delay aging in animals and humans. However, meta-analyses of human clinical trials performed to treat and prevent various diseases with antioxidant supplements indicate that they have no effect on, or may even increase, mortality.

Mitochondrial Dysfunction Aging is characterized by altered mitochondrial production of ATP and oxygen-derived free radicals. This leads to a vicious cycle mediated by accumulation of oxidative injury to mitochondrial proteins and DNA. With age, the number of mitochondria in cells decreases and there is an increase in their size (megamitochondria) associated with other structural changes including vacuolization and disrupted cristae. These morphological aging changes are linked with decreased activity of mitochondrial complexes I, II, and IV and decreased ATP production. Of all of the complexes involved in ATP production, the activity of complex IV (COX) is usually reported to be most impaired in old age. Reduced energy production is linked with generation of hydrogen peroxide and superoxide radicals leading to oxidative injury to mitochondrial DNA and accumulation of carbonylated mitochondrial proteins and mitochondrial lipoperoxides. As well as being implicated in the aging process, common geriatric syndromes including sarcopenia, frailty, and cognitive impairment are associated with mitochondrial dysfunction.

Telomere Shortening and Replicative Senescence Cells that are isolated from animal tissue and grown in culture only divide for a certain number of times before entering a senescent phase. This number of divisions is known as the Hayflick limit and tends to be less in cells isolated from older animals compared to younger animals. It has been suggested that aging in vivo might in part be secondary to some cells ceasing to divide because they have reached their Hayflick limit. Senescent cells produce a variety of cytokines, chemokines, and proteases, termed the senescence-associated secretory phenotype (SASP), that are major drivers of age-related inflammation. Eliminating senescent cells delayed aging in mice. On the other hand, cellular senescence may have a role in preventing proliferation of cells at risk of malignant transformation. One mechanism for replicative senescence relates to telomeres. Telomeres are repeat sequences of DNA at the end of linear chromosomes that shorten by around 50–200 base pairs during each cell division by mitosis. Once telomeres become too short, cell division can no longer occur. This mechanism contributes to the Hayflick limit and has been called the cellular clock. There are some studies that suggest that the length of telomeres in circulating leukocytes (leukocyte telomere length, LTL) decreases with age in humans. However, the aging process also occurs in tissues that do not undergo repeated cell division such as neurons.

Altered Gene Expression, Epigenetics, and microRNA The expression of many genes and proteins changes during the aging process. These changes are complicated and vary between species and tissue. Such heterogeneity reflects increasing dysregulation of gene expression with age while appearing to exclude a programmed and/or uniform response. With old age, reductions in the expression of genes and proteins associated with mitochondrial function and increased expression of those involved with inflammation, genome repair, and oxidative stress are noted. Several factors control the regulation of gene and protein expression that change with aging. These include the epigenetic state of the chromosomes (e.g., DNA methylation and histone acetylation) and microRNAs (miRNAs). DNA methylation correlates with age, although the pattern of change is complex. Histone acetylation is regulated by many enzymes including Sirtuin 1 (SIRT1), a protein that has marked effects on aging and the response to dietary restriction in many species. miRNAs are a very large group of noncoding lengths of RNA (18–25 nucleotides) that inhibit translation of multiple different mRNAs through binding their 3′ untranslated regions (3′UTRs). The expression of miRNAs usually decreases with aging and is altered in some age-related diseases. Specific miRNAs

linked with aging pathways include miR-21 (associated with target of rapamycin pathway) and miR-1 (associated with insulin/insulin-like growth factor 1 pathway).

Impaired Autophagy and Proteostasis Cells can remove damaged macromolecules and organelles in a number of ways, often generating cellular energy as a by-product. Intracellular degradation is undertaken by the lysosomal system and the ubiquitin proteasomal system. Both are impaired with aging, leading to the accumulation of waste products that alter cellular functions. Such waste products include lipofuscin, a brown auto-fluorescent pigment found within lysosomes of most cells in old age and often considered to be one of the most characteristic histological features of aging cells. Lysosomes are organelles that contain proteases, lipases, glycases, and nucleotidases that degrade intracellular macromolecules, membrane components, organelles, and some pathogens through a process called autophagy. The lysosomal process most impaired with aging is macroautophagy, which is regulated by numerous autophagy-related genes. Proteostasis refers to the maintenance of protein quality through regulation of protein folding and protein degradation. Chaperones orchestrate appropriate folding of proteins while degradation involves ubiquitin tagging, proteases, and the unfolded protein response. With aging damaged, aggregated and misfolded proteins increase because of age-related changes in proteostasis. This may contribute to the aggregation of proteins such as tau, β-amyloid, α-synuclein in age-related neurodegenerative diseases such as dementia and Parkinson's disease.

AGING CHANGES IN SPECIFIC TISSUES THAT PREDISPOSE TO DISEASE

Aging changes in some tissues increase susceptibility to age-related disease as a secondary or downstream phenomenon (Fig. 463-3). In humans, this includes, but is not limited to, the immune system (leading to increased infections and autoimmunity), hepatic detoxification (leading to increased exposure to disease-inducing endobiotics and xenobiotics), the endocrine system (leading to hypogonadism and bone disease), and the vascular system (leading to segmental or global ischemic changes in many tissues).

Inflamm-aging and Immunosenescence Old age is associated with increased background levels of inflammation including blood measurements of C reactive protein (CRP), erythrocyte sedimentation rate (ESR), and cytokines such as interleukin 6 (IL-6) and tumor necrosis factor alpha (TNFα). This has been termed "inflamm-aging" and elevated IL-6 in particular has been associated with frailty and dementia. T cells are less numerous because of age-related atrophy of the thymus, while B cells overproduce autoantibodies, leading to the age-related increase in autoimmune diseases and gammopathies. Thus, older people are generally considered to be immunucompromised and have reduced responses to infection (fever, leukocytosis) with increased mortality.

Detoxification and the Liver Old age is associated with impaired detoxification of various disease-causing endobiotics (e.g., lipoproteins) and xenobiotics (e.g., neurotoxins and carcinogens) leading to increased systemic exposure. In humans, the liver is the major organ for the clearance of such toxins. Hepatic clearance of many substrates is reduced in old age as a consequence of reduced hepatic blood flow, impaired hepatic microcirculation and, in some cases, reduced expression of xenobiotic metabolizing enzymes. These changes in hepatic detoxification also increase the likelihood of increased blood levels of, and adverse reactions to, medications.

Endocrine System Hormonal changes with aging have been a focus for aging research for over a century, partly because of the erroneous belief that supplementation with sex hormones will delay aging and rejuvenate older people. There are age-related reductions in sex steroids, growth hormone, IGF-1, and dehydroepiandrosterone (DHEA). These hormonal changes may contribute to some features of aging such as sarcopenia and osteoporosis but also provide protection against cancer and cardiovascular disease. Adverse effects of long-term hormonal supplementation outweigh any potential beneficial effects on life span.

Vascular Changes There is a continuum from vascular aging through to atherosclerotic disease, present in many, but not all, older people. Vascular aging changes overlap with the early stages of hypertension and atherosclerosis, with increasing arterial stiffness and vascular resistance. This contributes to myocardial ischemia and strokes but also appears to be associated with geriatric conditions such as dementia, sarcopenia, and osteoporosis. In these conditions, impaired exchange between blood and tissues is a common pathogenic factor. For example, the risk of Alzheimer's disease and dementia is increased in patients with risk factors for vascular disease, and pathological evidence for microvascular changes is seen in postmortem studies of brains of people with established Alzheimer's disease. Similarly, strong epidemiological links have been found between osteoporosis and standard vascular risk factors, while significant age-associated changes are in the microcirculation of osteoporotic bone. Sarcopenia might also be related to the effects of age on the muscle vasculature, which is altered in old age. The sinusoidal microcirculation of the liver becomes markedly altered during aging (pseudocapillarization), which influences hepatic uptake of lipoproteins, insulin, and other substrates. In fact, it has often been overlooked that in his original exposition of the free radical theory of aging, Harman proposed that the primary target of oxidative stress was the vasculature and that many aging changes were secondary to impaired exchange across the damaged blood vessels.

GENETIC INFLUENCES ON AGING

There is variability in aging and life span in populations of genetically identical species such as mice that are housed in the same environment. The heritability of life span in human twin studies is estimated to be only 25% (although there is stronger hereditary contribution to extreme longevity). These two observations indicate that the cause of aging is unlikely to lie only within the DNA code. On the other hand, genetic studies initially undertaken in the nematode worm *C. elegans* and, more recently, in models from yeast to mice have shown that manipulating genes can have profound effects on the rate of aging. Perhaps surprisingly, this can often be generated by variability in *single* genes, and for some genetic mechanisms, there is very strong evolutionary conservation.

Genetic Progeroid Syndromes There are a few very rare, genetic premature aging conditions that are called progeroid syndromes. These conditions recapitulate some, but not all, age-related diseases and senescent phenotypes. They are mostly caused by impairment of genome and nuclear maintenance. These syndromes include the following:

- *Werner's syndrome*. This is an autosomal recessive condition caused by a mutation in the *Werner's (WRN)* gene. This gene codes for a RecQ helicase, which unwinds DNA for both repair and replication. It is typically diagnosed in teen years and is associated with premature onset of atherosclerosis, osteoporosis, cancers, and diabetes with death by age of 50 years.
- *Hutchinson–Gilford progeria syndrome (HGPS)*. This usually occurs as a de novo, noninherited mutation in the lamin A gene (*LMNA*) leading to an abnormal protein called progerin. LMNA is required for the nuclear lamina, which provides structural support to the nucleus. Marked development changes are obvious in infancy with subsequent onset of atherosclerosis, kidney failure, and scleroderma-like features and death during the teen years. Lamin A-dependent nuclear defects have been reported in normal human aging.
- *Cockayne syndrome*. This includes a number of autosomal recessive disorders with features such as impaired neurological growth, photosensitivity (xeroderma pigmentosum), and death during childhood years. These are caused by mutations in the genes for DNA excision repair proteins, *ERCC-6* and *ERCC-8*.

Gene Studies in Long-Lived Humans The main genes that have been consistently associated with increased longevity in human candidate gene studies are *APOE* and *FOXO3A*. ApoE is an apoprotein

found in chylomicrons while the ApoE4 isoform is a risk factor for Alzheimer's disease and cardiovascular disease, which might explain its association with reduced life span. FOXO3A is a transcription factor involved in the insulin/IGF-1 pathway, and its homolog in *C. elegans*, daf16, has a marked impact on aging in these nematodes. Genome-wide association studies (GWASs) of centenarians have confirmed the association of longevity with *APOE*. GWAS has been used to identify a range of other single nucleotide polymorphisms (SNPs) that might be associated with longevity including SNPs in the sirtuin genes and the progeroid syndrome genes, *LMNA* and *WRN*. Gene set analysis of GWAS studies has shown that both the insulin/IGF-1 signaling pathway and the telomere maintenance pathway are associated with longevity.

One group of particular interest are people with Laron-type dwarfism. These people have mutations in the growth hormone receptor that causes severe growth hormone resistance. In mice, similar knockout of the growth hormone receptor (GHRKO mice, Methuselah mice) is associated with extremely long life. Therefore, subjects with Laron syndrome have been carefully studied and it was found that they have very low rates of cancer and diabetes mellitus, and possibly, longer lives.

Nutrient-Sensing Pathways Many living things have evolved to respond to periods of nutritional shortage and famine by increasing cellular resilience and delaying reproduction until food supply becomes abundant once again. This increases the chances of reproductive success and survival of offspring. Lifelong food shortage, often termed "caloric restriction (CR)" (or "dietary restriction"), increases life span and delays aging in many animals, probably as a side effect of this famine response. Many of the genes and pathways that regulate the way that cells respond to nutritional undersupply have been identified, initially in yeast and *C. elegans*. In general, manipulation of these pathways (through genetic knockout or overexpression, or pharmacological agonists and antagonists) alters the aging benefits of CR, and in some cases, the life span of animals on normal diets. These pathways are all very influential cellular "switches" that control a wide range of key functions including protein translation, autophagy, mitochondrial function and bioenergetics, and the cellular metabolism of fats, proteins, and carbohydrates. The discovery of these nutrient-sensing pathways has led to targets for pharmacological extension of life span. The main nutrient-sensing pathways that influence aging and responses to CR include:

- *SIRT1*. The activity of SIRT1 is regulated by levels of reduced nicotinamide adenine dinucleotide (NAD^+), which are increased when cellular energy stores are depleted. Important downstream targets include PGC-1α and Nrf2, which act on mitochondrial biogenesis.
- *Mechanistic target of rapamycin (mTOR)*. mTOR is activated by branched chain amino acids, providing a link to dietary protein intake. It has two main components, mTORC1 and mTORC2, of which mTORC1 is most relevant to aging. Key downstream targets of mTOR of relevance to aging include the tuberous sclerosis protein (TSC) and 4EBP1, which influences protein production.
- *5′ adenosine monophosphate-activated protein kinase (AMPK)*. AMPK is activated by increased levels of AMP, which reflect cellular energy status.
- *Insulin signaling and IGF-1/growth hormone (IIS)*. These two pathways are usually considered together because they overlap in lower animals and have diverged only in higher animals. They respond to carbohydrate and protein intake. An important downstream target for this pathway is a transcription factor called FOXO.
- *Fibroblast growth factor 21 (FGF21)*. FGF21 is produced mostly by the liver in response to CR and reduced protein intake.

Mitochondrial Genes Mitochondrial function is influenced by genes located both in the mitochondria (mtDNA) and the nucleus. mtDNA is considered to have a prokaryotic origin and is highly conserved across taxa. It forms a circular loop of 16,569 nucleotides in humans. Aging is associated with increased frequency of mutations in mtDNA as a consequence of its high exposure to oxygen-derived free radicals and relatively inefficient DNA repair machinery. Nuclear DNA encodes ~1000–1500 genes for mitochondrial function including genes involved with oxidative phosphorylation, mitochondrial metabolic pathways, and enzymes required for biogenesis. These genes are thought to have originated in mtDNA but subsequently translocated to the nucleus and, unlike mtDNA genes, their sequence is stable with aging.

Genetic manipulation of mitochondrial genes in animals influences aging and life span. In *C. elegans*, many mutants with defective electron transfer chain function have increased life span. The mtDNA "mutator" mice which lack the mtDNA proofreading enzyme have increased mtDNA mutations and premature aging, while overexpression of mitochondrial uncoupling proteins leads to longer life span. In humans, hereditary variability in mtDNA is associated with diseases (mitochondriopathies such as Leigh's disease) and aging. For example, in Europeans, mitochondrial DNA haplogroup J (haplogroups are combinations of genetic variants that exist in specific populations) is associated with longevity, and haplogroup D is overrepresented in Asian centenarians.

Nuclear DNA Genomic DNA damage accumulates in cells with aging while genetic progeroid conditions such as Werner's syndrome and HGPS are associated with impaired DNA maintenance and repair. Age-related DNA changes include mutations, chromosomal aneuploidy, copy number variations, and telomere shortening. Apart from telomere attrition, these changes are random and vary between cells, and may contribute to age-related cancers.

STRATEGIES THAT INCREASE HEALTH SPAN AND DELAY AGING

Aging is an intrinsic feature of human life whose manipulation has fascinated humans ever since becoming conscious of their own existence. Several long-term experimental interventions (e.g., resveratrol, rapamycin, spermidine, and metformin) may open doors for corresponding pharmacological strategies. Surprisingly, most of the effective aging interventions proposed converge on only a few molecular pathways: nutrient signaling, mitochondrial proteostasis, and the autophagic machinery.

Life span is inevitably accompanied by functional decline, steady increase of a plethora of chronic diseases, and ultimately death. For millennia, it has been a dream of mankind to prolong both life span and health span. Developed countries have profited from the medical improvements and their transfer to public health care systems—as well as from better living conditions derived from their socioeconomic power—to achieve remarkable increases in life expectancy during the last century. In the United States, the percentage of the population aged ≥65 years is projected to increase from 13% in 2010 to 19.3% in 2030. However, old age remains the main risk factor for major life-threatening disorders, and the number of people suffering from age-related diseases is anticipated to almost double over the next two decades. The prevalence of age-related pathologies represents a major threat as well as an economic burden that urgently needs effective interventions.

Molecules, drugs, and other interventions that might decelerate aging processes continue to raise interest among both the general public and scientists of all biological and medical fields. Over the past two decades, this interest has taken root in the fact that many of the molecular mechanisms underlying aging are interconnected and linked with pathways that cause disease, including cancer, cardiovascular and neurodegenerative disorders. Unfortunately, among the many proposed aging interventions, only a few have reached a certain age themselves. Results often lack reproducibility because of a simple inherent problem: interventions in aging research take a lifetime to assess. Experiments lasting the lifetime of animal models are prone to develop artifacts, increasing the possibilities and time windows for experimental discrepancies. Some inconsistencies in the field arise from overinterpreting life span-shortening models and scenarios as being accelerated aging.

Many substances and interventions have been claimed to be antiaging throughout history and into the present. In the following sections, interventions will be restricted to those that meet the following highly selective criteria: (1) promotion of life span and/or health span, (2) validation in at least three model organisms, and (3) confirmation by at least three different laboratories. These include: (1) CR and fasting regimens, (2) some pharmacotherapies (resveratrol, rapamycin, spermidine, and metformin), and (3) exercise.

Caloric Restriction One of the most important and robust interventions that delays aging is CR. This outcome has been recorded in rodents, dogs, worms, flies, yeasts, monkeys, and prokaryotes. CR is defined as a reduction in the total caloric intake, usually of about 30% and without malnutrition. CR reduces the release of growth factors such as growth hormone, insulin, and IGF-1, which are activated by nutrients and have been shown to accelerate aging and enhance the probability for mortality in many organisms. Yet the effects of CR on aging were first discovered by McCay in 1935 long before the effects of such hormones and growth factors on aging were recognized. The cellular pathways that mediate this remarkable response have been explored in many experimental models. These include the nutrient sensing pathways (mTOR, AMPK, insulin/IGF-1, and sirtuins) as well as transcription factors (FOXO in *D. melanogaster* and daf-16 in *C. elegans*). The transcription factor Nrf2 appears to confer most of the anticancer properties of CR in mice, even though it is dispensable for life span extension.

The effects of CR in monkeys have been assessed in two studies with different outcomes: one study observed prolonged life while the other did not. However, both studies confirmed that CR increases health span by reducing the risk for diabetes, cardiovascular disease, and cancer. In humans, CR is associated with increased life and health span. This is most convincingly demonstrated in Okinawa, Japan, where one of the most long-lived human populations resides. In comparison to the rest of the Japanese population, Okinawan people usually combine an above-average amount of daily exercise with a below-average food intake. However, when Okinawan families move to Brazil, they adopt a Western lifestyle that affects both exercise and nutrition, causing a rise in weight and a reduction in life expectancy by nearly two decades. In the Biosphere II project, where volunteers lived together for 24 months undergoing an unforeseen severe CR, there were improvements in insulin, blood sugar, glycated hemoglobin, cholesterol levels, and blood pressure—all outcomes that would be expected to benefit life span. CR changes many aspects of human aging that might influence life span such as the transcriptome, hormonal status (especially IGF-1 and thyroid hormones), oxidative stress, inflammation, mitochondrial function, glucose homeostasis, and cardiometabolic risk factors. Epigenetic modifications are an emerging target for CR.

It must be noted that maintaining CR and avoiding malnutrition is not only arduous in humans but is also linked with substantial side effects. For instance, prolonged reduction of calorie intake may decrease fertility and libido, impair wound healing, reduce the potential to combat infections, and lead to amenorrhea and osteoporosis.

While extreme obesity (body mass index [BMI] >35) leads to a 29% increased risk of dying, people with BMI in the overweight range seem to have reduced mortality, at least in population studies of middle-aged and older subjects. People with a BMI in the overweight range seem more able to counteract and respond to disease, trauma, and infection, whereas CR impairs healing and immune responses. On the other hand, BMI is an insufficient denominator of body and body fat composition. A well-trained athlete may have an equivalent BMI compared to a fat person because of the higher muscle mass density. The waist:hip ratio is a much better indicator for body fat and an excellent and stringent predictor for the risk to die from cardiovascular disease: the lower the waist:hip ratio, the lower the risk.

PERIODIC FASTING How can CR be translated to humans in a socially and medically feasible way? A whole series of periodic fasting regimens are asserting themselves as suitable strategies, among them the alternate-day fasting diet, the "five:two" intermittent fasting diet, and a 48-h fast once or twice each month. Periodic fasting is psychologically more viable, lacks some of the negative side effects and is only accompanied by minimal weight loss.

It is striking that many cultures implement periodic fasting rituals, for example Buddhists, Christians, Hindus, Jews, Muslims, and some African animistic religions. It could be speculated that a selective advantage of fasting versus nonfasting populations is conferred by health-promoting attributes of religious routines that periodically limit caloric intake. Indeed, several lines of evidence indicate that intermittent fasting regimens exert antiaging effects. For example, improved morbidity and longevity were observed among Spanish home nursing residents who underwent alternate-day fasting. Even rats subjected to alternate-day fasting live up to 83% longer than normally fed control animals and one 24-h fasting period every 4 days is sufficient to generate life span extension.

Repeated fasting and eating cycles may circumvent the negative side effects of sustained CR. This strategy may even yield effects despite extreme overeating during the nonfasting periods. In a spectacular experiment, mice fed a high-fat diet in a time-restricted manner, i.e., with regular fasting breaks, showed reduced inflammation markers, no fatty liver and were slim in comparison to mice with equivalent total calorie consumption but ad libitum. From an evolutionary point of view, this kind of feeding pattern may reflect mammalian adaptation to food availability: overeating in times of nutrient availability (e.g., after a hunting success) and starvation in between. This is how some indigenous peoples who have avoided Western lifestyles live today; those who have been investigated show limited signs of age-induced diseases such as cancer, neurodegeneration, diabetes, cardiovascular disease, and hypertension.

Fasting exerts beneficial effects on health span by minimizing the risk of developing age-related diseases including hypertension, neurodegeneration, cancer, and cardiovascular diseases. The most effective and rapid repercussion of fasting is reduction in hypertension. Two weeks of water-only fasting resulted in a blood pressure below 120/80 mmHg in 82% of subjects with borderline hypertension. Ten days of fasting cured all hypertensive patients who had been taking antihypertensive medication previously.

Periodic fasting dampens the consequences of many age-related neurodegenerative diseases (Alzheimer's disease, Parkinson's disease, Huntington's disease, and frontotemporal dementia but not amyotrophic lateral sclerosis in mouse models). Fasting cycles are as effective as chemotherapy against certain tumors in mice. In a combination with chemotherapy, fasting protected mice against the negative side effects of chemotherapeutic drugs, while it enhances their efficacy against tumors. Combining fasting and chemotherapy rendered 20–60% mice cancer-free when inoculated with highly aggressive tumors like glioblastoma or pancreatic tumors, which have 100% mortality even with chemotherapy.

Pharmacological Interventions to Delay Aging and Increase Life Span Virtually all obese people know that stable weight reduction will reduce their elevated risk of cardiometabolic disease and enhance their overall survival, yet only 20% of overweight individuals are able to lose 10% weight for a period of at least 1 year. Even in the most motivated people (such as the "Cronies" who deliberately attempt long-term CR in order to extend their lives), long-term CR is extremely difficult. Thus, focus has been directed at the possibility of developing medicines that replicate the beneficial effects of CR without the need for reducing food intake ("CR-mimetics," **Fig. 463-5**):

- *Resveratrol*. Resveratrol, an agonist of SIRT1, is a polyphenol that is found in grapes and in red wine. The potential of resveratrol to promote life span was first identified in yeast, and it has gathered fame since, at least in part because it has been suggested to be responsible for the so-called French paradox whereby wine reduces some of the cardiometabolic risks of a high fat diet. Resveratrol has been reported to increase life span in many lower order species such as yeast, fruit flies, worms as well as mice on high-fat diets. In

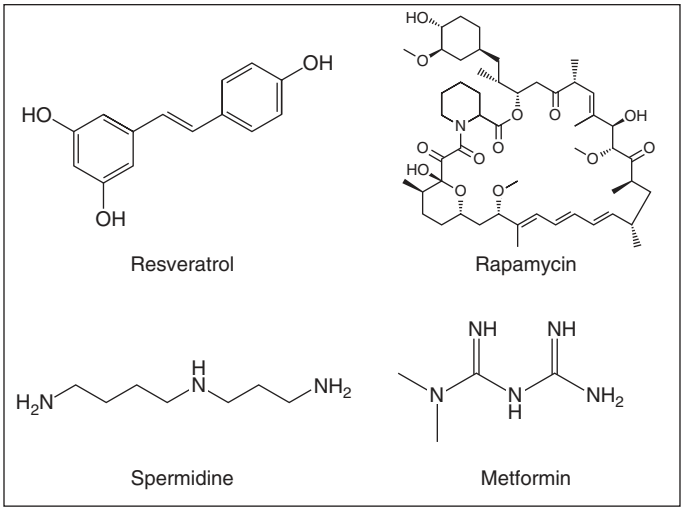

FIGURE 463-5 Chemical structure of four agents (resveratrol, rapamycin, spermidine, and metformin) that have been shown to delay aging in experimental animal models.

monkeys fed with a diet high in sugar and fat, resveratrol had beneficial outcomes related to inflammation and cardiometabolic parameters. Some studies in humans have also shown improvements in cardiometabolic function while others have not. Gene expression studies in animals and humans reveal that resveratrol mimics some of the metabolic and gene expression changes of CR.

- *Rapamycin*. Rapamycin, an inhibitor of mTOR, was originally discovered on the Easter Island (Rapa Nui, hence its name) as a bacterial secretion with antibiotic properties. Before its immersion in the antiaging field, rapamycin was known as an immunosuppressant and cancer chemotherapeutic in humans. Rapamycin extends life span in all organisms tested so far, including yeast, flies, worms, and mice. However, the potential utility of rapamycin for human life span extension is likely to be limited by adverse effects related to immunosuppression, wound healing, proteinuria, and hypercholesterolemia, among others. An alternative strategy may be intermittent rapamycin feeding, which was found to increase mouse life span.
- *Spermidine*. Spermidine is a physiological polyamine that induces autophagy-mediated life span extension in yeast, flies, and worms. Spermidine levels decrease during life of virtually all organisms including humans, with the stunning exception of centenarians. Oral administration of spermidine or upregulation of bacterial polyamine production in the gut both lead to life span extension in short-lived mouse models. Spermidine has also been found to have beneficial effects on neurodegeneration probably by increasing transcription of genes involved in autophagy.
- *Metformin*. Metformin, an activator of AMPK, is a biguanide first isolated from the French lilac that is widely used for the treatment of type 2 diabetes mellitus. Metformin decreases hepatic gluconeogenesis and increases insulin sensitivity. Metformin has other actions including inhibition of mTOR and mitochondrial complex I, and activation of the transcription factor SKN-1/Nrf2. Metformin increases life span in different mouse strains including female mouse strains predisposed to high incidence of mammary tumors. At a biochemical level, metformin supplementation is associated with reduced oxidative damage and inflammation and mimics the some of the gene expression changes seen with CR.

Exercise and Physical Activity In humans and animals, regular exercise reduces the risk of morbidity and mortality. Given that cardiovascular diseases are the dominant cause of aging in humans but not in mice, the effects on human health may be even stronger than those seen in mouse experiments. An increase in aerobic exercise capacity, which declines during aging, is associated with favorable effects on blood pressure, lipids, glucose tolerance, bone density, and depression in older people. Likewise, exercise training protects against aging disorders such as cardiovascular diseases, diabetes mellitus, and osteoporosis. Exercise is the only treatment that can prevent or even reverse sarcopenia (age-related muscle wasting). Even moderate or low levels of exercise (30 min walking per day) have significant protective effects in obese subjects. In older people, regular physical activity has been found to increase the duration of independent living.

While clearly promoting health and quality of life, regular exercise does not extend life span. Furthermore, the combination of exercise with CR has no additive effect on maximal life span in rodents. On the other hand, alternate-day fasting with exercise is more beneficial for the muscle mass than single treatments alone. In nonobese humans, exercise combined with CR has synergistic effects on insulin sensitivity and inflammation. From the evolutionary perspective, the responses to hunger and exercise are linked: when food is scarce, increased activity is required to hunt and gather.

Hormesis The term hormesis describes the, at first sight paradoxical, protective effects conferred by the exposure to low doses of stressors or toxins (or as Nietzsche stated "What does not kill me makes me stronger"). Adaptive stress responses elicited by noxious agents (chemical, thermal, or radioactive) precondition an organism rendering it resistant to subsequent higher and otherwise lethal doses of the same trigger. Hormetic stressors have been found to influence aging and life span presumably by increasing cellular resilience to factors that might contribute to aging such as oxidative stress.

Yeast cells that have been exposed to low doses oxidative stress exhibit a marked antistress response that inhibits death following exposure to lethal doses of oxidants. During ischemic preconditioning in humans, short periods of ischemia protect the brain and the heart against a more severe deprivation of oxygen and subsequent reperfusion-induced oxidative stress. Similarly, the lifelong and periodic exposure to various stressors can inhibit or retard the aging process. Consistent with this concept, heat or mild doses of oxidative stress can lead to life span extension in *C. elegans*. CR can also be considered as a type of hormetic stress that results in the activation of antistress transcription factors (Rim15, Gis1, and Msn2/Msn4 in yeast and FOXO in mammals) that enhance the expression of free radical-scavenging factors and heat shock proteins.

CONCLUSIONS

Clinicians need to understand aging biology in order to better manage those people who are elderly. Moreover, there is an urgent need to develop strategies based on aging biology that delay aging, reduce the onset of age-related disorders, and increase health span for future generations. Interventions related to nutrition and those drugs that act on nutrient-sensing pathways are being developed and, in some cases, are already being tested in humans.

464 Clinical Problems Associated with the Aging Process

Joseph G. Ouslander, Bernardo Reyes

AGING AND GERIATRIC CARE

Demographics of Aging and its Implications for Geriatric Care The United States and other countries will continue to experience a rapid increase in the number of older adults who seek health care. The most rapidly growing segment of the population in the United States and many other developed countries is those aged >80 years (Fig. 464-1). Sex composition of the aging population around the world is also expected to change. Although females outlive males, an improvement in survival of the oldest males could result in more balanced sex distribution in the geriatric population in the future.

Based on the United Nations' 2015 World Population Aging Report, in high-income countries, consumption of health care resources will be most affected by the shift in the age distribution of the population over the next several decades. The World Health Organization continues to work actively to raise awareness of the changes necessary in current health care systems beyond increments in their budgets. Planning is increasingly being based on expected levels of disability and comorbidity. As lifespan increases, efforts should continue to focus on promoting healthy aging to reduce the burden of disability in health care systems all over the world.

Implications of the Aging Population for Health Care Systems and System-Based Practice The geriatric population requires different approaches to care for several reasons. For example, acute illnesses are most often not treated in isolation, but in the context of multiple co-morbidities. Close to half of those aged >80 have three, and about one-third have four or more chronic conditions (Fig. 464-2). Functional disabilities are prevalent (Fig. 464-3), which require careful attention in the evaluation of the older patient, along with assessment of social supports available for assistance when needed for independent and safe living.

Effectively caring for the geriatric population requires consideration of several key principles:

1. Aging is not a disease; normal aging changes generally do not cause symptoms, but do increase susceptibility to many diseases and conditions due to diminished physiologic reserve (which has been termed "homeostenosis"). Aging is also associated with greater heterogeneity in virtually every measureable variable. Lab values outside the "normal" range are more common and may not reflect pathology.
2. Medical conditions are commonly multiple ("multi-morbidity") and multifactorial in origin, requiring a comprehensive approach to evaluation and management.
3. Many potentially reversible and treatable conditions are underdiagnosed and under-evaluated in this population, such as fall risk, urinary incontinence, and elder abuse and neglect; simple screening tools can help detect them.
4. Similarly, cognitive and affective disorders (e.g. mild cognitive impairment, dementia, depression, anxiety) are common and may be undiagnosed in early stages; simple screening tools can help detect them.
5. Iatrogenic illnesses are common, especially related to adverse drug reactions and immobility and related deconditioning and other complications.
6. Functional ability and quality of life, as opposed to cure, are key goals of care.
7. Social history, social support, and patient preferences are critical to treat older people in a safe and person-centered manner.
8. Effective geriatric care requires inter-professional collaboration among many different disciplines.
9. Geriatric care is provided largely outside the hospital—at home, in skilled nursing and assisted living settings; and attention to care transitions between settings is essential for effective care.
10. Ethical issues, palliative care, and end-of-life care are critical aspects of caring for the geriatric population.

In this chapter, these key principles are highlighted. The reader is referred to textbooks of geriatric medicine for more details on each of

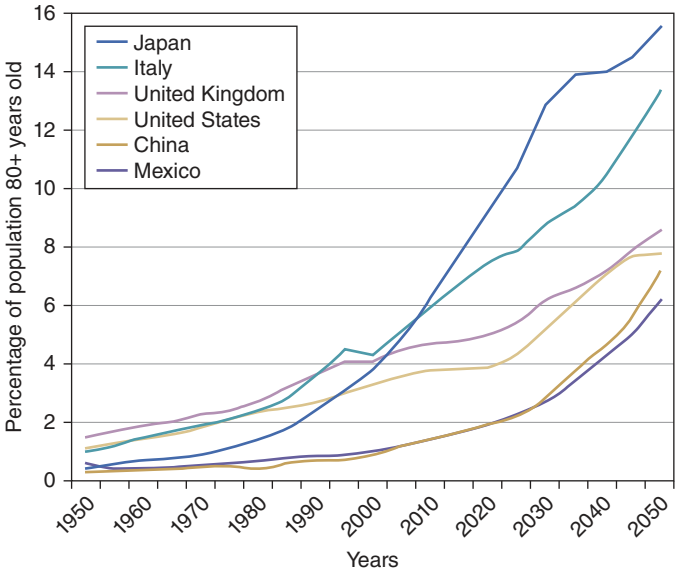

FIGURE 464-1 Percentage of the population age >80 years from 1950 to 2050 in representative nations. *(Updated data available at https://esa.un.org/unpd/wpp/Graphs/DemographicProfiles/. Accessed December 30, 2016.)*

the principles, and the management of common diseases and conditions in this population.

Models of Geriatric Care and Care Transitions Several innovative models of care have been developed over the last three decades designed to provide high quality and effective care for the burgeoning geriatric population with multi-morbidity, functional and cognitive impairment, and challenges with social support. These include outpatient comprehensive geriatric assessment programs, inpatient acute care for the elderly (ACE) units and consultation services, and home-based programs such as Geriatric Resources for Assessment and Care of Elders (GRACE), Home Based Primary Care (in the VA system), and Independence at Home. These models of care are assuming greater importance in the emerging era of value-based purchasing for health care services. While they may be challenging and inefficient to implement in the Medicare fee-for-service system, they may also result in improved care and lower costs overall as Medicare shifts from fee-for-service to other models of reimbursement, such as accountable care organizations, bundled payment programs, and increasing the number of older people enrolled in Medicare managed care.

Improving transitions of care between settings has become a major focus of the federal government, health systems, hospitals, post-acute (PAC) and long-term care (LTC) organizations and programs, physicians, and other health care professionals. Geriatric patients are especially vulnerable to complications at the time of discharge from an acute medical or psychiatric hospital, as well as at the time of discharge from a PAC facility (skilled nursing facility [SNF]; acute rehabilitation or long-term hospital) or home care program. With the increasing role of hospitalists and physicians who specialize in SNF care, medical care for geriatric patients has become fragmented at the time transitions, creating opportunities for communication problems and medical errors. Changes in reimbursement and financial penalties for high rates of hospital readmissions have driven the development of many care transition interventions (Table 464-1). These interventions involve inter-professional collaboration and a variety of strategies targeted at making care transitions safer, and reducing unnecessary return visits to the emergency department, hospital readmissions, and related complications and costs.

Inter-Professional Teams and Co-Managed Care The complexity of caring for the aging population is more evident during a hospitalization due to a new acute illness or exacerbation of pre-existing chronic conditions. Inter-professional teams integrate different areas of expertise with the aim of providing patient-centered care. Physicians should understand and respect the roles of nurses, physical, occupational, and speech therapists, nutritionists, pharmacists, psychologists, social workers, clergy, and other direct care staff. The evolution of inter-professional teams has resulted in a comprehensive approach to care by opening channels of communication between these health professionals from different disciplines.

TABLE 464-1 Examples Care Transitions Interventions

INTERVENTION	WEBSITE	CORE INTERVENTIONS
Re-Engineered Discharge (Project RED) (Jack et al: 2009)	*https://www.bu.edu/fammed/projectred/*	"Discharge advocate" performs the following: · Facilitates patient education and understanding · Performs medication reconciliation · Coordinates post-discharge appointments and communication with primary care provider (PCP) · Calls patient 2–3 days post-discharge
Transitional Care Model (Naylor et al: 2004; Naylor et al: 1999)	*https://www.nursing.upenn.edu/ncth/transitional-care-model/*	Advanced practice nurse performs the following: · Coordinates patient care pre- and post-discharge · Assesses each patient's needs; engages and activates the patient and family · Facilitates communication among patient, family, and health care providers · Conducts regular home visits and telephone support after discharge
Care Transitions Program® (Coleman et al: 2004)	*http://www.caretransitions.org*	"Transition Coach" performs the following: · Facilitates improved self-management skills including medication management and how to respond to warning signs/symptoms. · Makes post-discharge home visits and phone calls.
Better Outcomes for Older Adults through Safe Transitions (BOOST) (Hansen et al: 2013)	*http://www.hospitalmedicine.org/Web/Quality_Innovation/Implementation_Toolkits/Project_BOOST/Web/Quality___Innovation/Implementation_Toolkit/Boost/Overview.aspx?hkey=09496d80-8dae-4790-af72-efed8c3e3161*	Includes toolkit facilitating the following: · Comprehensive identification and assessment of high-risk patients · Patient/caregiver education · Enhanced communication with post-hospitalization care providers · Follow-up phone call with patient post-discharge
Interventions to Reduce Acute Care Transfers (INTERACT) (Ouslander et al: 2013)	*https://interact.fau.edu*	Includes tools for skilled nursing, assisted living and home health care including: · Quality Improvement · Communication · Decision support · Advance care planning

"Huddles" are a mechanism of enhanced communication for inter-professional teams. The implementation of efficient huddles has been associated with improved safety and better utilization of resources by predicting patient needs and making appropriate changes in staffing and care plans. Huddles can also help identify potential threats to patient care, such as socioeconomic challenges that can make care plans ineffective of even harmful.

Another strategy for enhanced communication and collaboration in the care of complex geriatric patients is "Co-Managed Medicine." In this model, internists serve as part of a multispecialty team of physicians (that often include surgeons) that provides daily assessments, addresses medical comorbidities, and facilitates transitions of care; thereby enhancing the typical consultant model. Co-managed medicine is another example of how enhanced communication between different providers improves outcomes, avoids common complications, and saves resources. In the era of person-centered care and value-based medicine, effective co-managed medicine appears to deliver consistently high quality care at a lower cost. Since the rise of hospitalist-based care, the use of co-managed care has increased significantly. Hip fracture co-management, as well as trauma co-management, and collaborations between internists and geriatricians are examples of this strategy.

FUNDAMENTALS OF GERIATRIC CARE

Person-Centered Care Person-centered care is a critical concept in caring for older people because of the complexity of their medical, functional, and psychosocial problems, and in many instances the lack of rigorous data on the most effective strategies for caring for specific conditions in patients with multi-morbidity. Thus, decision-making on goals and approaches to care must account for patient and family preferences and goals, values, perception of risk, prognosis, and other individual factors. For almost any condition, from common disorders such as hypertension and diabetes, to geriatric syndromes such as fall risk and urinary incontinence, the answer to how best to treat medical conditions in an older patient with multi-morbidity does not only depend on evidence-based medicine—it also depends on careful weighing of the factors listed above. In everyday practice with complex older patients, a focus on improving or maintaining function and independence, quality of life, comfort, and dignity will be consistent with patient and family goals.

The American Geriatrics Society (AGS) identifies the following elements as key to person-centered care: (1) an individualized, goal-oriented care plan based on the person's preferences; (2) ongoing review of the person's goals and care plan; (3) continual information sharing and integrated communication; (4) education and training for providers and, when appropriate, the person and those important to the person; and (5) performance measurement and quality improvement using feedback from the person and caregivers. Several tools are available to assist in implementing person-centered care, including estimation of prognosis (e.g., "ePrognosis"), and "choosing wisely" recommendations from the AGS and AMDA—The Society for Post-Acute and Long-Term Care Medicine. Examples of these recommendations that are relevant to internal medicine practice are illustrated in Table 464-2.

TABLE 464-2 Examples of Choosing Wisely Recommendations Helpful in Implementing Person-Centered Care in Complex Geriatric Patients

- Don't recommend percutaneous feeding tubes in patients with advanced dementia; instead offer oral assisted feeding.
- Don't use antipsychotics as the first choice to treat behavioral and psychological symptoms of dementia.
- Avoid using medications other than metformin to achieve hemoglobin A1c <7.5% in most older adults; moderate control is generally better.
- Don't use benzodiazepines or other sedative-hypnotics in older adults as first choice for insomnia, agitation or delirium.
- Don't use antimicrobials to treat bacteriuria in older adults unless specific urinary tract symptoms are present.
- Don't prescribe cholinesterase inhibitors for dementia without periodic assessment for perceived cognitive benefits and adverse gastrointestinal effects.
- Don't recommend screening for breast, colorectal, prostate or lung cancer without considering life expectancy and the risks of testing, over-diagnosis and overtreatment.
- Don't routinely prescribe lipid-lowering medications in individuals with a limited life expectancy.
- Don't obtain a *Clostridium difficile* toxin test to confirm "cure" if symptoms have resolved.
- Don't recommend aggressive or hospital-level care for a frail elder without a clear understanding of the individual's goals of care and the possible benefits and burdens.

Evaluation of the Geriatric Patient • GERIATRIC ASSESSMENT A series of screening questions can be useful as a "geriatric review of systems" in clinical practice with older patients because of the importance and high prevalence of functional impairments and disabilities, limited social support to assist with functional limitations, cognitive and affective disorders, and geriatric conditions that may go undetected and cause patient safety issues and complications (Table 464-3). These questions may be especially helpful in conducting annual Medicare "Wellness Visits." Positive responses to one or more of the screening questions for each item should prompt consideration of further assessments, many of which can be accomplished using standard and validated tools available on the internet, such as activities of daily living scales, depression scales, sleep questionnaires, and mental status examinations.

EVALUATION OF MEDICAL DECISION-MAKING CAPACITY Key aspects of decision-making in older adults are illustrated in Fig. 464-4. Including the patient in the consent process for any treatment is the foundation of patient autonomy and person-centered care. Because aging is associated with an increasing potential to develop cognitive impairment, determination of decision-making capacity is important not only to protect the patients against potential abuse, but also to preserve autonomy when possible and when it is not, that an appropriate surrogate decision-making process is followed. Assessing for capacity is usually triggered by specific circumstances (e.g., the need for invasive diagnostic testing or surgery). Determination of decision-making capacity limited to medical circumstances should be differentiated from declaring a patient "incompetent" to make all decisions. Declaring someone incompetent is a legal definition and usually is reserved for court settings. Another caveat about evaluating decision-making capacity is distinguishing lack of capacity from poorly presented information, sensory impairment, and/or low level of literacy. The clinician should corroborate that the patient has received all the necessary information, comprehends the information provided, and there are no major auditory or visual impairments. For geriatric patients, it is important to determine if the patient uses hearing aids of prescription glasses and they are available for their use.

Standard tests of cognitive function such as the Mini Mental State Examination correlate poorly with capacity to consent for specific interventions. Several standardized tools have been validated to determine decision-making capacity. The MacArthur Competence Assessment Tool-Treatment (MacCAT-T) is a structured tool that has been validated, but it is lengthy and can be difficult to administer in some patients. The Capacity to Consent to Treatment Instrument (CCTI) is another tool that has been validated in patients with mild to moderate Alzheimer's disease. It is structured in two different vignettes and the patient is asked to answer a series of questions. The test has high inter-rater reliability and validity.

EVALUATION OF THE OLDER DRIVER For many older adults in the United States, driving is essential for maintaining independence and driving cessation is associated with negative outcomes including social isolation and depression. On the other hand, older adults have the highest risk of being involved in fatal crashes with up to a nine-time higher risk for those 85 years old compared to younger people. Older people should be routinely assessed for their driving status and if they have been in

TABLE 464-3 Examples of Screening Questions and Tools and Strategies for Further Evaluation of Social Support, Functional Status, Geriatric Syndromes, and Cognition and Affect

GERIATRIC ASSESSMENT DOMAINS		RECOMMENDED SCREENS	FURTHER ASSESSMENT FOR POSITIVE SCREEN*
SOCIAL	**Social Support**	Do you live alone? Do you have a caregiver? Are you a caregiver?	• Consider referral to a social worker • Refer to Area Agency on Aging
	Elder Neglect/Abuse	Do you ever feel unsafe where you live? Has anyone ever threatened or hurt you? Has anyone been taking your money without your permission?	• Consider referral to a social worker and/or Adult protective services
	Advance Directives	Would you like information or forms for a power of attorney for health care? Would you like information on a living will?	• Discussion on advance directives • Physician Orders for Life-Sustaining Treatment (POLST) (or MOLST or POST)
FUNCTIONAL	**Functional Status**	Do you need assistance with shopping or finances? Do you need assistance with bathing or taking a shower?	• Instrumental Activities of Daily Living (ADL) Scale • Basic ADL Scale
	Driving	Do you still drive? If yes: While driving, have you had an accident in the past 6 months? Driving concerns by family member?	• Vision testing • Consider occupational therapy and/or formal driving evaluation
	Vision	Do you have trouble seeing, reading, or watching TV? (with glasses, if used)	• Vision testing • Consider referral for eye exam
	Hearing	Do you have difficulty hearing conversation in a quiet room? Unable to hear whisper test 6 inches away?	• Check for cerumen in ear canals and remove if impacted • Hearing Handicap Inventory • Consider audiology referral
GERIATRIC SYNDROMES	**Medications**	Do you take 5 or more routine medications? Do you understand the reason for each of your medications?	• Match medications with diagnoses • Consider reducing doses, stopping drugs, adherence aides, and/or consultation with a pharmacist
	Fall Risk	Have you fallen in the past year? Are you afraid of falling? Do you have trouble climbing stairs or rising from chairs?	• "Get Up and Go" test • Consider full Fall Assessment • Consider Physical Therapy Evaluation • Consider Home Safety Assessment
	Continence	Do you have any trouble with your bladder? Do you lose urine or stool when you do not want to? Do you wear pads or adult diapers?	• Consider full continence Assessment • 3 IQ Questionnaire (women) • American Urological Association (AUA) 7 symptom inventory (men)
	Weight Loss	Weight <100 pounds or Unintentional weight loss >10 pounds over 6 months?	• Assess for common risk factors for malnutrition • Consider referral to dietician for nutritional evaluation
	Sleep	Do you often feel sleepy during the day? Do you have difficulty falling asleep at night?	• Epworth Sleepiness Scale or Pittsburgh Sleep Index • Consider referral for sleep evaluation
	Pain	Are you experiencing pain or discomfort?	• Pain Assessment
	Alcohol Abuse	Do you drink > 2 drinks / day?	• AUDIT-C
COGNITION AND AFFECT	**Depression**	Do you often feel sad or depressed? Have you lost pleasure in doing things over the past few months?	• PHQ – 9 or Geriatric Depression Scale • Screen for suicide risk
	Cognition	Self-reported memory loss? Cognitive screen positive? (3-item recall and Clock Draw test "Mini-Cog") Confusion Assessment (CAM) for delirium	• Montreal Cognitive Assessment or Mini Mental State Examination • If diagnosis is unclear, consider neuropsychological testing

Source: Adapted from RL Kane et al: *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

any car crashes, as well as for sensory, functional, and cognitive impairments that can make driving unsafe (Table 464-3). Like many geriatric conditions described below, many different types of drugs can impair various aspects of driving performance, and should be carefully considered in older people who continue to drive **(Table 464-4)**.

Suspected driving impairment can be a source of conflict between the patient (who wants to maintain independence), the family (who may want their relative to continue driving due to lack of other transportation; or may be concerned about their safety, or both) and the physician (who is concerned about the patient's, passengers', and other drivers' safety). There is liability involved in these decisions, since any states do not require driving re-testing for all older drivers, and many require physicians to report older people who they believe are unsafe drivers. Evaluation of driving should be inter-professional and aimed to first try to correct any reversible causes of losing driving skills, such as vision and hearing impairment. Although tests of executive function such as the Trails B have been associated with poor driving performance, no single screening test predicts unsafe driving.

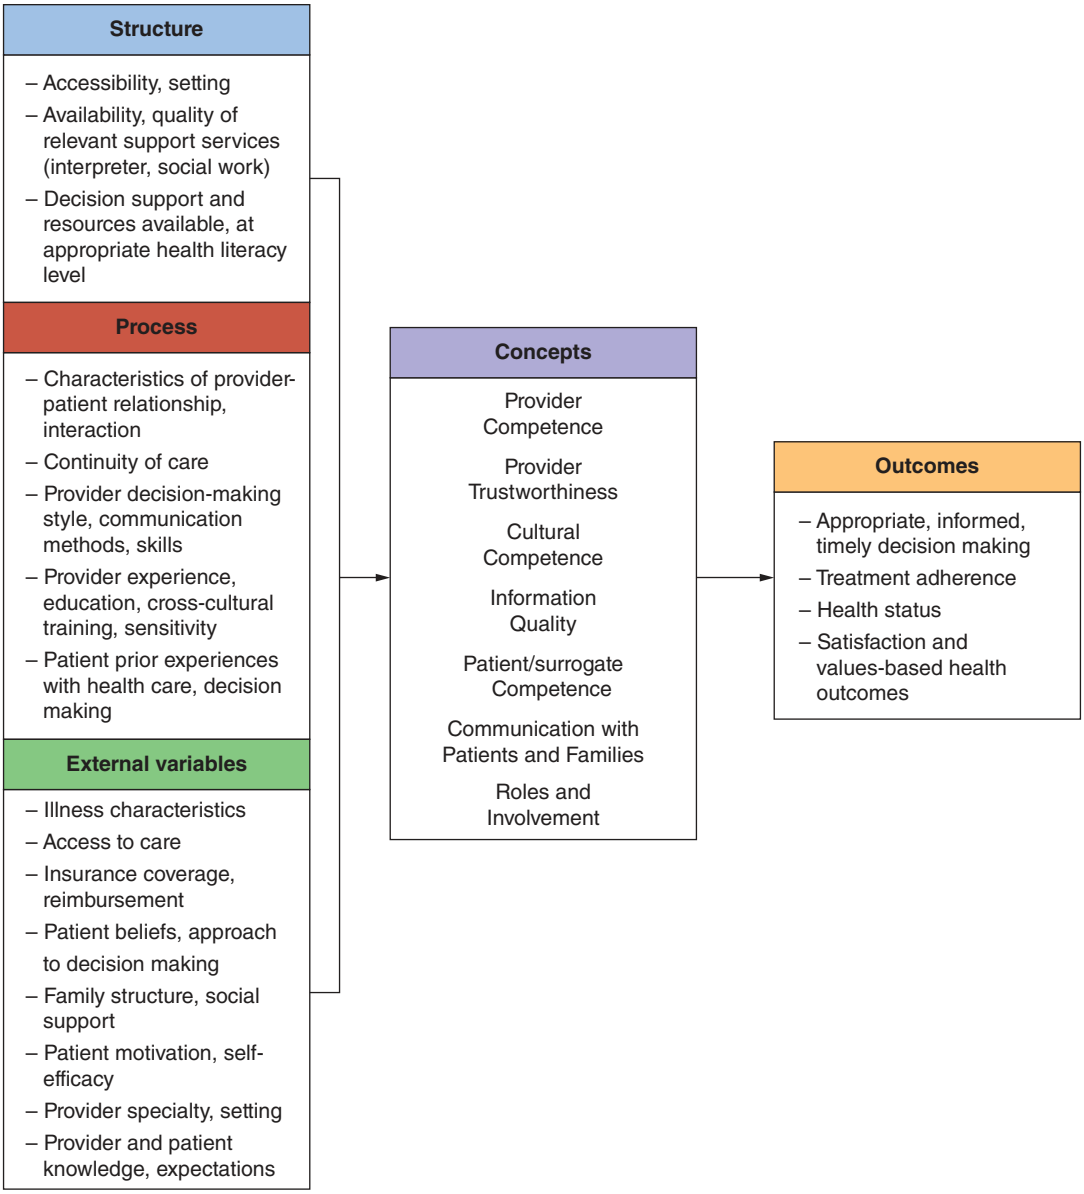

FIGURE 464-4 Key aspects of decision-making in older adults. *(From SM Dy, SP Tanjala: Key concepts relevant to quality of complex and shared decision-making in health care: A literature review. Soc Sci Med 74:582, 2012.)*

A combination of neuropsychological testing by a psychologist, and on-road testing by a trained occupational therapist can provide the physician with essential input in making the difficult decision on driving cessation. The AGS and the U.S. Department of Transportation's National Highway Traffic Safety Administration have updated a "Physician's Guide to Assessing and Counseling Older Drivers," which can be helpful to practicing clinicians and is available on the AGS website (see "Further Reading").

TABLE 464-4 Medications with Strong Potential to Affect Driving

Anticholinergics
Anticonvulsants
Antidepressants
Antiemetics
Antihistamines
Antihypertensives
Antiparkinsonian agents
Antipsychotics
Benzodiazepines and other sedatives/anxiolytics/hypnotics
Muscle relaxants
Narcotic analgesics
Stimulants
Other agents with significant anticholinergic properties

INTERPRETATION OF DIAGNOSTIC TESTS Atypical presentations of medical conditions are a common feature of geriatric medicine. Physiologic changes associated with aging can affect the results of common diagnostic tests as well. The large variation of many physiologic measures that is associated with normal aging makes establishing what is "normal" for many tests challenging. For this reason, the results of several diagnostic tests must be interpreted with caution. Examples include creatinine clearance, pulmonary function, and sedimentation rate (which can confound the diagnosis of polymyalgia). Ambulatory cardiac monitoring may identify a variety of arrhythmias, but they have a high incidence in older people and must be linked with symptoms before considering potentially toxic or invasive treatment. Musculoskeletal imaging, such as an MRI of the spine, may reveal multiple abnormalities that may or may not be related to symptoms. For the most part, however, abnormal diagnostic tests require further evaluation in older patients, unless further evaluation would not lead to a change in the goals of care and treatment plan. Examples include low hemoglobin levels, abnormal

thyroid function tests, age/sex/weight adjusted creatinine clearance, and elevated liver function tests; these examples do not result from normal aging and generally indicate a physiologic abnormality resulting from a disease or disorder that may or may not be reversible.

Prevention in Older Adults • AGE-APPROPRIATE SCREENING

Screening tests for specific diseases, as opposed to screening for geriatric conditions requires a careful person-centered approach. The focus of preventive medicine depends heavily on the ability to identify those who are at risk for specific conditions **(see Chap. 4)**. Several professional societies have provided guidance regarding specific tests in older adults **(Table 464-5)**. An important caveat about screening to prevent disease in older patients (e.g., colonoscopy for colon cancer; PAP smears; PSA testing) is that abnormal results may lead to subsequent testing and treatment among individuals who will not suffer morbidity or mortality from the disease because of limited life expectancy. Thus, geriatric patients pose a significant challenge for deciding what screening tests could offer a reasonable ratio of benefit and risk as well as being cost-effective. The *ePrognosis.com* website is a very helpful tool in these determinations.

VACCINATIONS The use of vaccines in older adults is aimed at creating immunity against common infections that could lead to serious complications, as well as for rebuilding previously obtained immunity. Currently, the CDC recommends routine vaccination against influenza, pneumococcus and shingles as they are prevalent in this age group. Other countries in Europe and Asia have similar trends on vaccinations with small variances.

SEXUALLY TRANSMITTED DISEASES (STDS) Although most STDs occur in younger people **(see Chap. 131)**, a portion of older adults have high-risk sexual behavior. Most Americans remain sexually active in their sixties and seventies, and up to a quarter of individuals in their eighties consider themselves sexually active. Sexually active older adults may have a lower awareness of the need for safe sexual practices, such as the risks of multiple sexual partners and condom use. The incidence of STDs in older people is still relatively low. Individuals born in the United States between 1945 and 1965 are at higher risk of having hepatitis C due to lack of awareness of the disease and lack of implementation of universal precautions before the 1980s for blood transfusions. Other factors that could affect such risk are use of intravenous drugs and unprotected sex with multiple partners. The prevalence of tertiary syphilis is higher than newly contracted syphilis in older adults. The incidence of gonococcal infection decreases with age. Nonetheless, patients presenting with symptoms compatible with syphilis or gonococcal infection (cervicitis, urethritis, proctitis, epididymitis) should be screened for high-risk sexual behavior and educated if necessary. Clinical symptoms of herpes simplex infection and the possibility of becoming contagious also decrease with age. As ulcerative lesions are less frequent, HSV-2 specific serologic testing should be considered for patients with recurrent nonspecific genital symptoms. Therapy should not be started unless the patients are symptomatic.

Almost 3 million patients aged >50 live with HIV. Since the introduction of HAART, life expectancy of patients with HIV has increased, resulting in a significant increase in the number of older adults living with the disease. De novo infections have also contributed to the rising number of HIV cases in older adults. The low rate of condom use and lack of knowledge of the disease play a key role in the transmission rate. Age is an independent predictor of HIV progression and associated mortality. There are no specific age-specific guidelines for treating HIV. Like all other conditions, there is a higher incidence of medication-related side effects in older patients, especially those with other comorbidities and on multiple other medications, and this should be considered in treatment decisions.

Treatment of Common Diseases in the Geriatric Population • HYPERTENSION

There have been several clinical trials demonstrating the benefits of hypertension treatment on the reduction of risk of cardiovascular events in older people. Nonetheless, blood pressure targets remain controversial. The balance between the cardiovascular protective benefits versus the risk of treatment-related adverse events must be considered in individual patients based on their comorbidities. For example, hypotension and postural hypotension related to antihypertensive therapy are common causes of near-syncope and falls and related injuries in the geriatric population, especially those with multi-morbidity. On the other hand, control of systolic blood pressure, in addition to preventing cardiovascular events, may reduce the burden of white matter changes in the brain, which are associated with gait abnormalities and falls and cognitive decline. However, no studies in older patients with multi-morbidity to date have documented any beneficial effects of tight control of hypertension on the incidence of falls and cognitive decline.

Two large studies (HYVET and SPRINT) have shed some light on these issues. HYVET was a multicenter study conducted in several countries involving ~3,800 patients ≥80 years old. The study demonstrated that active treatment of hypertension with a target of ≤150 mmHg not only significantly reduced the risk of stroke and heart failure, but also the mortality risk. As with other large hypertension studies like ALLHAT, there was a linear association between blood pressure and stroke reduction. Nonetheless, in the HYVET study, this association was less prominent as age increased. SPRINT was another large randomized trial targeting lowering systolic blood pressure to targets of <140 vs 120 mmHg (measured with an automated device) with a subgroup analysis in those aged ≥75 years. There were significant reductions in the primary end-point—a composite of cardiovascular disease events (including myocardial infarction, acute coronary syndrome, heart failure, stroke, or death from cardiovascular causes). However, it is critical to recognize that patients with diabetes, history of stroke or heart failure, and systolic blood pressure <110 mmHg after 1 min of standing were excluded from the SPRINT trial.

Overall, these data strongly suggest a person-centered approach to hypertension in the heterogeneous older population. For older patients with minimal comorbidity, no postural hypotension, and low risk of falls and volume depletion, the benefit/risk ratio favors lower targets for systolic blood pressure (<130 mmHg measured by a hand sphygmomanometer). However, for those with diabetes, heart failure, history of stroke, postural hypotension, careful treatment of blood pressure with higher systolic targets (< 150 mmHg) is probably a safer approach.

DIABETES The prevalence of diabetes in the older adult population is now over 25% and expected to increase due to adverse lifestyle changes and an increased incidence of obesity. Due to a lack of data on patients with multi-morbidity and those aged ≥80, and the high incidence of hypoglycemia in this population when treated with multiple hypoglycemic agents, the approach to management of diabetes requires a person-centered approach like that described for hypertension. Older diabetic patients are at significant risk of hypoglycemia because of potential medication errors, progressive decline in renal function, and inconsistent oral intake among other reasons. Hypoglycemic episodes are associated with progressive cognitive decline in older adults, especially those with existing cognitive impairment. On the other hand, uncontrolled diabetes is associated with an increased risk of all-cause dementia.

Data from randomized clinical trials that have largely excluded those aged ≥80 suggest that intensive glycemic control does not reduce major macrovascular events in older adults for at least 10 years or result in improved microvascular outcomes for at least 8 years, and at the same time increases the risk of severe hypoglycemia 1.5- to 3-fold. Thus, the AGS guideline on diabetes in older adults and the Choosing Wisely recommendations (Table 464-2) suggest that in most adults >65 years, the harms associated with a hemoglobin A1c (HbA1c) target <7.5% or >9% are likely to outweigh the benefits. These recommendations are consistent with the American Diabetes Association. Thus, the goals of treating diabetes in the geriatric population should be tailored to the patient's functional and medical status, social support, personal goals, perception of risk, and life expectancy. For specifics of treatment options, refer to **Table 464-6**. Regardless of the therapeutic goals for HbA1c, older diabetic patients should be regularly examined for the development of neuropathy, which can lead to the development of

TABLE 464-5 Recommendations for Primary Prevention Screening for Specific Diseases in Older Adults from Different Professional Societies

TYPE OF SCREENING	TEST	FREQUENCY	PROFESSIONAL SOCIETY ISSUING RECOMMENDATIONS		
			USPSTF[a]	ACS[b]	ACP[c]
Colorectal	Fecal occult blood test or fecal immunochemical test (FIT) or Sigmoidoscopy or Colonoscopy	Annual Every 5 y Every 10 y	Screen all adults age 50–75; prognosis may support screening individuals of age 76–85; not recommended for adults over age 85	Screen all adults age >50; discontinuing screening is reasonable in people with severe comorbidity that would preclude treatment	Screen all adults age 50–75 People with life expectancy <10 y should not be screened
Breast	Mammography	Every 1–2 y	Biennial screening all women age 50–74; evidence of benefits and harms is insufficient for women age >75	Annual screening starting at age 40; continue while in good health	ECOG[d] Annual screening starting at 40 y/o
Cervical	Pap smear HPV test	Pap only, every 3 y HPV + Pap, every 5 y	Screen women age 21–65; discontinue at age 65 if adequate prior screening	Screen women age 21–65; discontinue at age 65 if regular screening normal	Screening should stop at age 65 if evidence of negative adequate prior screening.
Lung	Low-dose CT scan	Annual	Screen age 55–80 current and former smokers with a 30+ pack-year smoking history; discontinue screening once a person has not smoked for 15 years or develops a health problem that limits their ability or willingness to have curative surgery	Screen 55–74-year-old current and former smokers in good health with a 30+ pack-year smoking history	ACCP[e] In settings that can deliver the comprehensive care provided to National Lung Screening Trial participants, offer screening to people age 55–74 current and former smokers with 30+ pack-year smoking history
Prostate	Prostate Specific Antigen (PSA)	1–2 y	Do not screen men for prostate cancer with PSA test	Screen men aged ≥50 with a life expectancy >10 y after discussion about the risks, benefits, and uncertainties of PSA screening. Follow-up screening should occur annually if PSA >2.5 ng/mL or biennially if PSA <2.5 ng/mL	AUA[f] Biennial PSA screening in men of 55–69 y with life expectancy >10–15 y, after shared decision-making discussions accounting for values and preferences
Osteoporosis	Dual-energy x-ray absorptiometry (DEXA) Measure height, preferably with a wall mounted stadiometer	Perform BMD testing 1 to 2 years after initiating medical therapy for osteoporosis and every 2 years annually thereafter	AAFP[g] Screening women age 65 or men age 70	NOF[h] Screen women age 65 and older and men age 70 and older; postmenopausal women and men age 50–69, based on risk factor profile; postmenopausal women and men age 50 and older who have had an adult age fracture	
Carotid Disease	Carotid ultrasound	Once	Society of Vascular Surgery Age >65, coronary artery disease, need for coronary bypass, symptomatic lower extremity arterial occlusive disease, history of tobacco use and high cholesterol would be appropriate risk factors to prompt ultrasound in patients with a bruit		
Coronary Artery Disease	Coronary Calcium Score (CCS)	Once	SCCT[i] Do not use CCS for patients with known CAD.	AHA/ACC[j] CCS of 0 may have a strong negative predictive value for coronary events in older adults.	
Abdominal Aortic Aneurysm	Abdominal Ultrasound	Once	USPSTF[a] Insufficient evidence to assess the balance of benefits and harms of screening women aged 65–75 years who have ever smoked.	AAFP[g] Recommended for men aged 65–75 years who have ever smoked.	
Diabetes	Fasting blood glucose, glucose tolerance test, or HbA1C	Annually	USPSTF[a] Abnormal blood glucose as part of cardiovascular risk assessment in adults aged 40–70 years who are overweight or obese	ADA[k] Screening people 45 years and older

TABLE 464-6 Recommendations and Considerations for Pharmacologic Therapy of Diabetes in Older Adults[a]

MEDICATION	RECOMMENDATIONS AND CONSIDERATIONS
Metformin	• Metformin is the first-line agent for older adults with type 2 diabetes • Recent studies suggest it may be used safely in patients with estimated glomerular filtration rate ≥30 mL/min/1.73 m^2 • Contraindicated in patients with advanced renal insufficiency or significant heart failure • May be temporarily discontinued before procedures or during hospitalizations and when acute illness compromises renal or liver function
Sodium–Glucose Cotransporter 2 Inhibitors	• Offer an oral route, which may be convenient for older adults • Long-term experience is limited despite the initial efficacy and safety data
Thiazolidinediones	• If used at all, should be used very cautiously in those with, or at risk for, congestive heart failure and those at risk for falls or fractures
Secretagogues	• Associated with hypoglycemia and should be used with caution • Shorter-duration sulfonylureas such as glipizide are preferred • Glyburide is a longer-duration and contraindicated in older adults
Incretin-Based Therapies	• Few side effects and minimal hypoglycemia, but costs may be a barrier • No evidence of increase in major adverse cardiovascular events • Glucagon-like peptide 1 receptor agonists are injectable, which require visual, motor, and cognitive skills • Associated with nausea, vomiting, diarrhea, and weight loss, which may not be desirable in some older patients, particularly those with cachexia
Insulin Therapy	• Requires that patients or their caregivers have good visual and motor skills and cognitive ability • Insulin doses should be titrated to meet individualized glycemic targets and to avoid hypoglycemia • Once-daily basal insulin injection therapy is associated with minimal side effects and may be a reasonable option in many older patients • Multiple daily injections of insulin may be too complex for the older patient with advanced diabetes complications, life-limiting comorbid illnesses, or limited functional status

[a]Based on recommendations from the American Diabetes Association 2017.

lesions on the feet that could become infected, as well as for retinopathy and vision loss that may require ophthalmologic intervention.

HYPERLIPIDEMIA While good evidence exists regarding the benefits of statins on primary cardiovascular risk prevention in patients ≤75 years old, for those aged >75 the data are very limited. The use of statins in those aged >75 or 80 for prevention of cardiovascular events and mortality is the subject of ongoing debate in the geriatric literature. No evidence from randomized controlled trials exists to guide statin initiation after age 80 years; treatment of hypercholesterolemia for patients at risk of atherosclerotic cardiovascular disease should start before they turn 80 years old. There are two other factors that make the use of statins in older adults controversial. First, the major benefits of statins have been demonstrated over long-term use; thus, life expectancy is a limiting factor to observe any meaningful change in outcomes. A substantial proportion of patients are maintained on statins at the end of life, but they can be safely discontinued. On the other hand, statins are well tolerated in older adults especially at moderate to low doses. Although many older adults on statins complain of muscle pain, the risk of myositis and rhabdomyolysis is increased mostly with the use of high doses; adverse effects of statins on cognitive function appear to be uncommon. Thus, some relatively healthy adults aged >75 years with life expectancy of >10 years may benefit, and the approach to hyperlipidemia should be person-centered in this population, as discussed for both hypertension and diabetes.

OSTEOARTHRITIS (OA) The approach to the management of symptomatic OA in the geriatric population differs from the approach in younger patients **(see Chaps. 363 and 364)** because of the risks of toxicity of nonsteroidal anti-inflammatory drugs (NSAIDs) in older patients. Nonpharmacologic interventions should be the first line of treatment. While some patients aged >65 years can tolerate NSAID use with concomitant protection from gastrointestinal (GI) bleeding with a proton pump inhibitor (PPI), this regimen exposes patients to two drugs with numerous potential adverse drug effects. NSAIDs are well known to be associated with GI bleeding; they are also associated with worsening renal function based on multiple potential mechanisms, and with sodium and fluid retention and exacerbation of hypertension and congestive heart failure. In addition, a substantial number of older patients are on anticoagulants or platelet aggregation inhibitors, which could further increase the risk of bleeding from NSAIDs. PPIs are associated with a higher incidence of pneumonia, osteoporosis, and *C. difficile*-associated diarrhea; and possibly with a higher risk of dementia.

Topical NSAIDs are better tolerated; lidocaine patches and nonprescription creams may also be effective. The AGS guideline on the management of chronic pain recommends that routine acetaminophen in doses up to 1 g four times daily should be the basis of pharmacologic treatment. Failure to respond could be followed up with careful trials of tramadol or a narcotic agent (started in a short-acting preparation) with appropriate attention to avoiding narcotic-induced constipation. Although prescription of narcotics is getting increasingly cumbersome because of high rates of abuse, this should not deter prescription of these agents to relieve pain and disability in older patients.

Many older patients respond well to a variety of non-pharmacologic interventions, including stretching, strengthening, timely and appropriate use of heat and ice, massage, swimming and whirlpool therapy, bracing, acupuncture, and therapeutic electrical stimulation. These interventions are best carried out under the supervision of physical therapists or other professionals with appropriate expertise to avoid injury. Surgical interventions, including replacement of major joints, have improved over the last several years, and even older patients with multi-morbidity may experience improved function and quality of life. Total knee replacement, for example, has been shown to be effective in generally healthy older patients, and should be considered in selected higher risk patients. "Pre-habilitation" with targeted strengthening and endurance exercises, and willingness to go through several weeks of post-operative physical therapy should be prerequisites for referring older patients for joint replacement.

CANCER More than half of new cases of cancer and mortality associated with it occur after the age of 65. There are limited data regarding older adults with multiple comorbid conditions and their response to cancer treatment. While only ~10% of clinical trials have had age-stratification analyses, the available evidence suggests that age alone is not a predictor of harm. Nonetheless, making treatment decisions is challenging due to both shorter life expectancy in older adults and the cumulative effect of multiple comorbidities. Thus, a person-centered approach is essential.

Older adults generally experience decreases in functional status after receiving chemotherapy. Most of this negative effect appears to be related to comorbidity and baseline functional status, rather than due

to age alone. For this reason, specialists in geriatric oncology have proposed using comprehensive geriatric assessment, including many of the issues addressed in Table 464-3 as a strategy to better predict which older adults will tolerate and benefit most from cancer treatment. Other considerations before making decisions about treatment plans should include socioeconomic factors. Lack of social support has been associated with poor outcomes after radiation and chemotherapy, especially in older women. Other important issues in cancer treatment planning include availability of transportation for treatments, economic and insurance status, the patient's ability to follow treatment plans, and family and social support available during therapy, when adverse effects and functional decline may occur.

GERIATRIC SYNDROMES AND CONDITIONS

In this section selected geriatric syndromes and conditions likely to be encountered by internists in hospital, clinic, office, PAC and LTC settings are discussed.

Falls • **EPIDEMIOLOGY AND IMPACT** Among all geriatric syndromes, falls are probably the most common that internists will encounter. Falls are responsible for potentially devastating consequences for function and quality of life, as well as mortality, in the geriatric population. About one in three older community-dwelling, and one in two older LTC residents fall annually; many more are at risk for falls. The impacts of falls include fear of falling with adverse effects on quality of life, painful injuries including hip and wrist fractures, subdural hematomas, and death. Falls are associated with loss of function and death within the year after a fall. For these reasons, internists should regularly screen older people for falling using questions such as: "Have you fallen in the past year?" "Are you afraid of falling?" "Do you have trouble climbing stairs or rising from chairs?" (Table 464-3).

EVALUATION The risks and causes of falls are multifactorial. Most older people at risk for a fall or who have suffered a fall have more than one potential underlying risk factor or cause. Many falls are labeled as "mechanical" and attributed to simply tripping or slipping. It is essential to recognize, however, that older people who trip or slip may have a variety of underlying reversible conditions that could have contributed to the event. Thus, a thorough evaluation of all falls is warranted. In addition to evaluating the patient who has fallen for injury, it is critical to determine, to the extent possible, whether the patient had a syncopal episode or a seizure, which dictate a very different approach to evaluation and management. As many as half of "unexplained falls" in older people with dementia (e.g., found on the floor) may be due to near-syncope or syncope related to postural hypotension.

Figure 464-5 illustrates an overview of the approach to an older person who reports a history of one or more fall in the past six months, and Table 464-7 provides more detail on the immediate evaluation of an older person who has fallen. **Chapter 23 provides more detail on the evaluation of gait and balance disorders.**

MANAGEMENT Table 464-8 illustrates approaches to the management of falls. Immediately after a fall injuries and underlying acute illnesses should be identified and treated. It is common practice for older patients who come to an Emergency Department with a history of a fall to have a brain imaging study. While this is understandable from a potential liability standpoint, it is also reasonable to avoid such studies if there is no history or signs of head trauma, neurologic symptoms or signs, or anticoagulation, and monitor the patient carefully over the

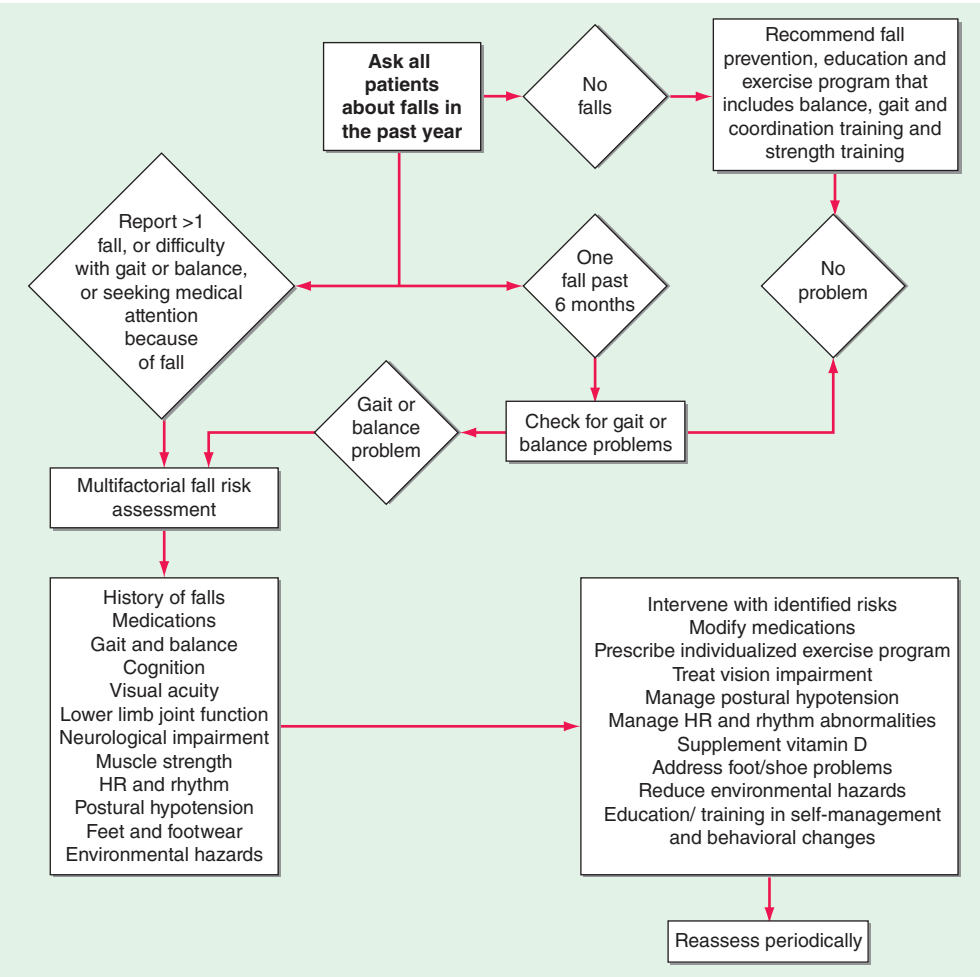

FIGURE 464-5 Algorithm depicting assessment and management of falls in older patients. HR, heart rate. *(From American Geriatrics Society and British Geriatrics Society: Clinical Practice Guideline for the Prevention of Falls in Older Persons. New York, American Geriatric Society, 2010.)*

TABLE 464-7 Evaluating the Older Person Who Falls—Immediate Post-Fall Evaluation

History

- Circumstances surrounding the fall
  - Relationship to changes in posture, turning of head, after a meal or medication intake, rushing to the toilet, nocturia, straining to urinate or defecate
  - Accidental trip or slip (note that many correctable factors can contribute to a reported "mechanical" fall – see text)
  - Hazards in the living environment (loose rugs; cords; unsafe steps; slippery floors; etc.)
- Premonitory or associated symptoms
  - Dizziness (lightheadedness vs vertigo); cardiovascular (postural lightheadedness, palpitations, chest pain, shortness of breath); focal neurological symptoms suggestive of stroke or transient ischemic attack (weakness, sensory disturbance, dysarthria, ataxia, aphasia); symptoms of a seizure (witnessed clinic movements; incontinence of urine or stool; tongue biting)
  - Symptoms over the previous few days that may have led to volume depletion (poor food/fluid intake; nausea/vomiting; diarrhea; urinary frequency/polyuria)
- Exclude loss of consciousness or seizure (may be difficult without a witness)
- Medications – chronic and within the few hours before the fall
  - Diuretics and other antihypertensive drugs
  - Nitrates
  - Drugs that cause bradycardia – beta blockers; cholinesterase inhibitors
  - Psychotropic - antipsychotics; hypnotics; sedatives; antidepressants
  - Antiparkinsonian
  - Hypoglycemic drugs
- Excessive alcohol intake

Physical Examination

- Exclude physical injury
  - Head trauma; hip range of motion; pubic bone tenderness; wrist pain; other signs of trauma
  - Bruising in patients on anticoagulants/platelet inhibitors
- Exclude acute illness
  - Vital signs
  - Postural vital signs (if feasible/safe)
  - Finger-stick glucose in diabetics
  - Poor skin turgor suggesting volume depletion (over chest; other areas unreliable)
  - Signs of an acute respiratory, cardiovascular, abdominal conditions
  - Focal neurological signs suggestive of stroke
- Signs of conditions that increase risk for falls
  - Poor visual acuity; use of bifocals
  - Limited range of motion of neck (to detect possible cervical arthritis/disk disease)
  - Cardiovascular—arrhythmias; carotid bruits; aortic stenosis; mitral insufficiency; heart failure
  - Degenerative joint disease in lower extremities causing pain, limited range of motion, and/or deformity
  - Podiatric conditions (calluses; bunions; ulcerations; poorly fitted, inappropriate, or unsafe shoes)
  - Neurological signs—lower extremity muscle weakness; peripheral neuropathy; tremor, rigidity, and/or bradykinesia suggestive of undiagnosed Parkinson's disease; cerebellar signs (abnormal heel to shin or heel tapping); abnormal reflexes that could reflect upper motor neuron disorder such as spinal cord compression or subdural hematoma; cognitive deficits that can result in poor judgement
  - Observation of gait and balance – simple get up and go test (see text) with observation for short steps, poor foot elevation, wide-based gait, multiple steps to turn 180 degrees; other abnormalities that might suggest normal pressure hydrocephalus (especially in combination with symptoms of incontinence and/or cognitive impairment)

Laboratory and/or Imaging Studies

- Should be guided by history and physical examination – common examples include:
  - Complete blood count, basic metabolic panel to exclude/verify acute illness
  - Urinalysis (only when additional symptoms of urinary tract infection present)
  - Electrocardiogram (in patients suspected of acute coronary syndrome or with significant known cardiovascular disease)
  - X-rays to exclude fractures
  - Brain imaging if signs present to exclude subdural hematoma, stroke
  - Cardiac monitoring in patients with history suggestive of syncope or near-syncope
  - Electroencephalography in patients with history suggestive of seizure

next 48–72 h for the development of specific indications for a brain imaging study.

Because the causes of and risk factors for falls are often multifactorial, management commonly requires multiple interventions in the same patient. Among the most common and effective interventions are physical therapy for strengthening and balance; Tai Chi has also been shown to be effective in multiple trials. Although many older people who fall are vitamin D–deficient, the role of vitamin D replacement in preventing falls, or preventing injuries from falls when combined with interventions such as strength and balance training is not clear. The risk/benefit ratio probably favors vitamin D replacement with at least 800 IU per day, but high dose vitamin D (60,000 IU in one oral dose monthly) has been associated with an increase in risk of falls. Patients who suffer a fracture after a fall should be investigated and treated for osteoporosis. Patients at high risk for recurrent falls and injuries should be encouraged to use a fall alert system; selected patients may benefit from hip protectors.

Polypharmacy • **EPIDEMIOLOGY AND IMPACT** Polypharmacy has been defined as the prescription of multiple medications using various thresholds (generally ranging from five up to nine simultaneous drugs), and has been identified as a major challenge in the geriatric

TABLE 464-8 Examples of Management for Underlying Causes of Falls in Older Patients

CAUSES	EXAMPLES OF TREATMENT
Cardiovascular	
Arrhythmias	Antiarrhythmic medication, ablation, pacemaker (depending on nature of arrhythmia)
Aortic stenosis with syncope or near syncope	Valve surgery (trans-catheter procedure if appropriate)
Postural hypotension	Reduce or eliminate hypotensive drugs Hydration, support stockings Medication (proamitine, fludrocortisone, droxidopa) Adaptive behaviors (e.g., pausing and getting up slowly)
Hypertension	Manage carefully to avoid hypotension and near syncope; control may be important in patients with periventricular white matter changes in preventing further gait disturbance
Neurologic	
Autonomic dysfunction with postural hypotension	As above
Cervical spondylosis (with spinal cord compression)	Neck brace; physical therapy; consider surgery
Parkinson disease	Antiparkinsonian drugs
Visual impairment	Ophthalmological/optometric evaluation and specific treatment
Seizure disorder	Anticonvulsants
Normal-pressure hydrocephalus	Surgery (ventricular-peritoneal shunt)
Dementia	Supervised activities Hazard-free environment
Benign positional vertigo	Habituation exercises Anti-vertiginous medication
Others	
Foot disorders	Podiatric evaluation and treatment
Gait and balance disorders	Properly fitted shoes Physical therapy Exercise with balance training (including Tai Chi where available)
Muscle weakness, deconditioning	Lower extremity strength training
Drug overuse (eg, sedatives, alcohol, other psychotropic drugs, antihypertensive)	Elimination of drug(s) when feasible
Vitamin D deficiency	Vitamin D supplementation
Recurrent falls	Fall alert system for those who live alone; hip protectors in selected patients

Source: Adapted from RL Kane et al: *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

population for decades. About 40% of the U.S. population aged ≥65 take 5–9 medications, and ~20% take 10 or more. Polypharmacy is an increasingly complex challenge because of the rising prevalence of multi-morbidity, a plethora of clinical practice guidelines, proliferation of medications that can effectively treat common geriatric conditions, and rising patient and family demand for medications due in part to television advertising and information available on the internet. For example, based on several condition specific clinical practice guidelines (which do not account for multi-morbidity), an 80-year-old person with multi-morbidity including diabetes, chronic obstructive lung disease, hypertension, osteoporosis, and degenerative joint disease might be prescribed an extremely complicated non-pharmacologic regimen and over a dozen medications with the potential for multiple drug-drug and drug-disease interactions.

Polypharmacy increases the risks associated with age-related changes in the pharmacology of many drugs, and the risk of adverse drug events (ADEs). ADEs cause over 100,000 hospitalizations per year; the main culprits are warfarin and other antiplatelet agents, and insulin and other hypoglycemic agents. Other categories of drugs are also involved, including cardiovascular drugs that can cause electrolyte and volume disturbances and hypotension, falls, and syncope; central nervous system drugs associated with altered mental status and falls; and antimicrobials which cause allergic reactions, diarrhea, and other ADEs.

EVALUATION All older patients should have careful medication reconciliation at each office or clinic visit, and especially at the time of care transitions, including acute hospitalization, hospital discharge, admission to a PAC facility or home health program, and discharge from a PAC facility to home. At each transition, all medications should be considered in terms of unclear diagnosis or indication, uncertain dose or route of administration, stop date, hold parameters, lab tests needed for monitoring, dosages different than the last care setting, medication duplication, medications that should be restarted, and the potential for drug-drug and drug-disease interactions. At each clinic or office visit for community-dwelling older people, possible ADEs, effectiveness of drug therapy, and adherence should be evaluated.

MANAGEMENT Table 464-9 lists several general recommendations for geriatric prescribing that should help make drug therapy more

TABLE 464-9 General Recommendations for Geriatric Prescribing

1. Evaluate geriatric patients thoroughly to identify all conditions that could (a) benefit from drug treatment; (b) be adversely affected by drug treatment; and (c) influence the efficacy of drug treatment
2. Manage medical conditions without drugs as often as possible
3. Know the pharmacology of the drug(s) being prescribed
4. Consider how the clinical status (e.g., renal function, hydration) of each patient could influence the pharmacology of the drug(s)
5. Avoid potentially serious adverse drug-drug interactions
6. For drugs or their active metabolites eliminated predominantly by the kidney, use a formula to approximate age-related changes in renal function and adjust dosages accordingly—the Cockcroft-Gault formula (below) is probably safer as it tends to underestimate creatinine clearance

$$\text{Creatinine clearance} = \frac{(140 - \text{age}) \times \text{body weight (kg)}}{72 \times \text{serum creatinine level}} \quad (\times 0.85 \text{ for women})$$

7. If there is a question about drug dosage, start with smaller doses and increase gradually until the drug is effective or intolerable side effects are observed
8. Drug blood concentrations can be helpful in monitoring several potentially toxic drugs used in the geriatric population
9. Help to ensure adherence by:
   a. Making drug regimens and instructions as simple as possible
   b. Using the same dosage schedule for all drugs whenever feasible (e.g., once or twice per day)
   c. Timing the doses in conjunction with a daily routine
   d. Paying attention to impaired cognitive function, diminished hearing, and poor vision when instructing patients and labeling prescriptions
   e. Instructing relatives and caregivers on the drug regimen
   f. Enlisting other health professionals (e.g., home health aides, pharmacists) to help ensure compliance
   g. Making sure the older patient can get to a pharmacist (or vice versa), can afford the prescriptions, and can open the container
   h. Using aids (such as special pillboxes and drug calendars) whenever appropriate
   i. Performing careful medication adjudication and patient/family education at the time of every hospital discharge
   j. Keeping updated medication records and review them at each visit
   k. Reviewing knowledge of and adherence with drug regimens regularly
10. Monitor older patients frequently for adherence, drug effectiveness, and adverse effects, and adjust drug therapy accordingly

Source: Adapted from RL Kane et al: *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

effective and safer in older patients, especially those with multimorbidity. Chapter 63 also provides information on general principles of clinical pharmacology. Because these patients often see multiple specialists, the internist should serve as the "quarterback" for all prescribing to help ensure adherence and minimize the potential for ADEs. In hospital, PAC, and LTC settings clinical pharmacists can be extremely helpful in achieving these recommendations and goals.

While there may be undertreatment of certain conditions in older people (such as osteoporosis, depression, and overactive bladder), more attention is now being paid to "de-prescribing." De-prescribing must be done carefully, especially at the time care transitions, when indications for specific drugs and patient preferences may not be clear. The American Geriatrics Society's updated Beers Criteria includes a comprehensive list of drugs that may be inappropriate in older people and the rationale for this rating. The STOPP criteria are also useful in identifying drugs that should be reconsidered on older people.

Several commonly prescribed drugs should be considered for "de-prescribing" efforts, including: (1) diuretics and hypotensive agents when patients have systolic hypotension or postural hypotension that can precipitate near-syncope and falls; (2) over-reliance on antianxiety and hypnotic medications, especially benzodiazepines; (3) psychotropic and other drugs with anticholinergic activity that can cause dry mouth, constipation, and increase the long-term risk of cognitive impairment; (4) PPIs with unclear indications because of numerous reported potential ADEs including increased risk of pneumonia, osteoporosis, and dementia; (5) cholinesterase inhibitors and memantine in patients with severe cognitive impairment who have been on them for years: and (6) hypoglycemic agents in patients with multi-morbidity who should not have tightly controlled blood sugar with increased risk of hypoglycemia; and (7) statins in patients with severe chronic illness who are near the end of life.

Careful de-prescribing is a critical aspect of person-centered care in the geriatric population. Several general principles, including some in Table 464-9, may assist with de-prescribing efforts, including: (1) ascertain all drugs the patient is currently taking and the reasons for each one; (2) consider overall risk of drug-induced harm in individual patients in determining the required intensity of deprescribing intervention; (3) assess each drug as to its current or future benefit potential compared with current or future harm or burden potential; (4) prioritize drugs for discontinuation that have the lowest benefit-harm ratio and lowest likelihood of adverse withdrawal reactions or disease rebound syndromes; and (5) implement a discontinuation regimen based on the pharmacology of the drug being discontinued, and monitor patients closely for improvement in outcomes or onset of adverse effects.

Cognitive Impairment—Delirium and Dementia

The reader is referred to other chapters in this text (Chapters 423–426) for detailed information on delirium and dementia in the overall population and among older patients specifically.

EPIDEMIOLOGY AND IMPACT Delirium occurs in up to 40% of hospitalized older patients, and is associated with increased morbidity, need for institutional care, and mortality in this population. While most episodes of delirium clear within a few days if the underlying cause(s) are identified and treated, delirium may persist for weeks, and in a few cases for months, after an acute hospitalization.

Normal aging does not cause impairment of cognitive function of sufficient severity to render an individual dysfunctional, which is the hallmark of a dementia syndrome. Slowed thinking and reaction time, mild recent memory loss, and impaired executive function can occur with increasing age and may or may not progress to dementia. Figure 464-6 illustrates the prevalence of memory impairment with increasing age. Just over 20% of people aged >70 in the United States have cognitive impairment without dementia (generally referred to as "Mild cognitive impairment [MCI])." Up to 15 to 20% of those diagnosed with MCI will progress to dementia over the course of a year; thus, most people with MCI will progress to dementia within 5 years. Therapeutic implications of MCI are subjects of intensive research.

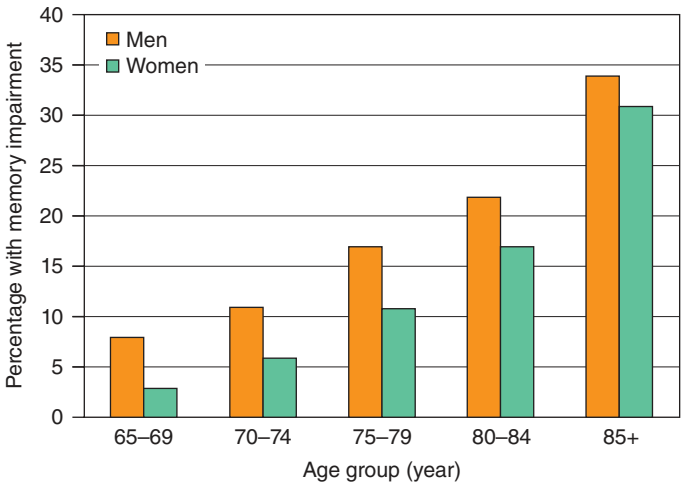

FIGURE 464-6 Rates of memory impairment in different age groups. The definition of "moderate or severe memory impairment" is 4 or fewer words recalled out of 20. *(Source: Health and Retirement Survey; details can be found at: http://hrsonline.isr.umich.edu/. Accessed December 30, 2016.)*

No non-pharmacological or pharmacological intervention has been shown to prevent progression to dementia.

The definitions of dementia syndromes (now also termed "major neurocognitive disorder") have been updated by the American Psychiatric Association. The prevalence of dementia increases with age; by age 85 between 30 and 40% have a dementia syndrome. Alzheimer's disease and vascular dementia, which often occur together based on pathologic studies, account for most dementias in older people. Dementia with Lewy bodies accounts for up to 25% of dementia, and is characterized by Parkinsonian features early in the disease (as opposed to dementia in Parkinson's disease, which generally occurs years after the onset of Parkinson's), personality changes, alterations in alertness and attention, and visual hallucinations that can cause paranoia. Most dementia syndromes are slowly progressive over several years; however, dementia is a terminal illness among patients who do not succumb to other comorbidities, and results in devastating loss of cognition and function in the later stages.

EVALUATION Regardless of setting, the new onset of delirium should be treated as a medical emergency because it can be the manifestation of an underlying critical illness. Figure 464-7 illustrates an overview of the assessment and management of impaired mental status and delirium in older hospitalized patients. The most validated evaluation for delirium is the Confusion Assessment Method, which requires an acute onset and fluctuating course *and* inattention *and* disorganized thinking *or* altered level of consciousness. Because the causes and risk factors for delirium are multifactorial, evaluation requires a careful history, physical examination, and selected laboratory studies based on the findings.

The benefits of screening older adults for cognitive impairment are controversial, but there are many interventions that may benefit patients and families early in the course of the disease (see below). Older patients in outpatient settings with complaints (or family reports of) early signs of cognitive impairment benefit from neuropsychological testing, which can help differentiate MCI and dementia, and identify concomitant factors such as depression and anxiety. The "Mini-Cog" is a sensitive screening tool for cognitive impairment, and consists of a 3-item recall test and clock drawing. Further evaluation of dementia includes a comprehensive history and physical examination, functional status assessment (since the diagnosis depends on impaired function), a brain imaging study, and selected laboratory tests, including a complete blood count, comprehensive metabolic panel, thyroid function tests, vitamin B12 level, and, if suspected tests for syphilis and human immunodeficiency virus antibodies.

MANAGEMENT Table 464-10 lists non-pharmacologic management strategies for various underlying risk factors and causes of delirium. Every attempt should be made to avoid or discontinue any medication

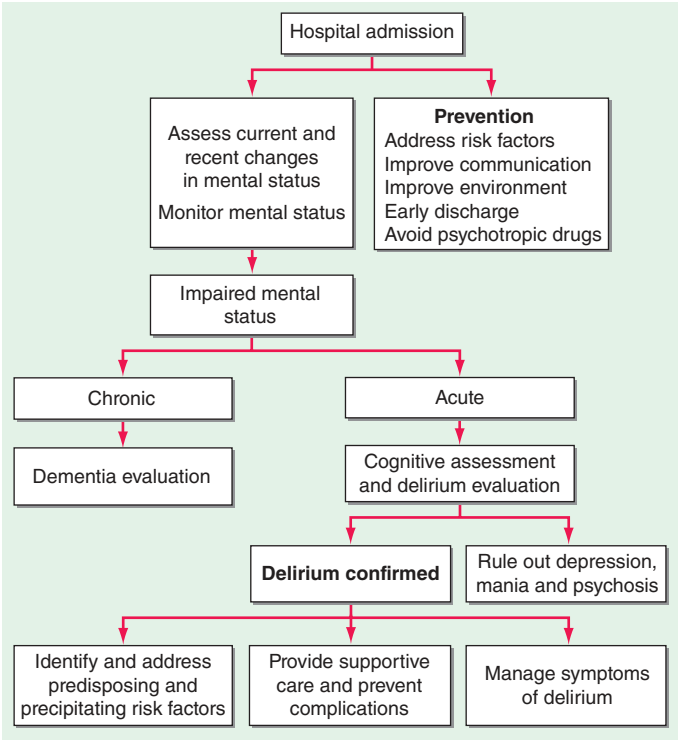

FIGURE 464-7 Algorithm depicting assessment and management of delirium in hospitalized older patients. *(Modified from SK Inouye: N Engl J Med 354:1157, 2006.)*

TABLE 464-10 Interventions for Risk Factors for Delirium

RISK FACTOR	INTERVENTION PROTOCOL
Cognitive impairment	• Orienting communication, including orientation board • Therapeutic activities program
Immobilization	• Early mobilization (e.g., ambulation or bedside exercises) • Minimizing immobilizing equipment (e.g., restraints, bladder catheters)
Psychoactive medications	• Restricted use of PRN sleep and psychoactive medications (e.g., sedative–hypnotics, narcotics, anticholinergic drugs) • Nonpharmacological protocols for management of sleep and anxiety
Sleep deprivation	• Noise-reduction strategies • Scheduling of night time medications, procedures, and nursing activities to allow uninterrupted period of sleep.
Vision impairment	• Provision of vision aids (e.g., magnifiers, special lighting) • Provision of adaptive equipment (e.g., illuminated phone dials, large-print books)
Hearing impairment	• Provision of amplifying devices; repair hearing aids • Instruct staff in communication methods
Dehydration	• Early recognition and volume repletion

Source: Data from SK Inouye et al: A clinical trial of a multicomponent intervention to prevent delirium in hospitalized older patients. N Engl J Med 340:669, 1990.

that may be worsening cognitive function in a delirious geriatric patient. This may not be possible, and in some patients, psychotropic drugs may be needed to treat delirium if the patient is a danger to themselves or others. Low dose haloperidol (0.25–0.5 mg) is generally recommended; more sedating antipsychotics and benzodiazepines should be avoided unless the goal is to put the patient to sleep for a short time. If a benzodiazepine is used, it should be short-acting and in a low dose.

Although the benefits of screening for cognitive impairment in older people are controversial, there are many non-pharmacologic interventions of older patients, their families, and other caregivers that may be beneficial **(Table 464-11)**. There are four basic approaches to the pharmacological treatment of dementia: (1) avoid drugs that can worsen cognitive function, mainly those with strong anticholinergic activity; (2) agents that enhance cognition and function; (3) drug treatment of coexisting depression, which is common throughout the course of dementia; and (4) pharmacological treatment of complications such as paranoia, delusions, psychosis, and behavioral symptoms such as agitation (verbal and physical). The use of antipsychotics to treat the neuropsychiatric symptoms of dementia is highly controversial. Most experts and guidelines recommend avoiding these drugs and using nonpharmacological strategies unless patients are a danger to themselves and others or if nonpharmacological interventions have failed. Patients with new or worsening behavioral symptoms associated with dementia should have a medical evaluation to identify potentially treatable precipitating conditions. Pain may be especially hard to detect, and if suspected, a therapeutic trial of acetaminophen should be considered.

The effectiveness of cholinesterase inhibitors and memantine in improving function and quality of life in patients with various types of dementia is controversial, and the potential benefits of these drugs versus their risks and costs must be weighed carefully to provide optimal person-centered care. The best evidence for effectiveness of cholinesterase inhibitors is in delaying progression of Alzheimer's disease and increasing the time before institutional placement is needed. Gastrointestinal side effects can be problematic and include nausea, vomiting, and diarrhea; nightmares can be bothersome as well. In addition to these bothersome side effects, cholinesterase inhibitors can cause bradycardia, and have been associated with syncope, injurious falls, and pacemaker placement. Memantine can cause dizziness, headache, confusion, and constipation. In one study, vitamin E was more effective than memantine in preventing functional decline in patients with Alzheimer's disease.

Urinary Incontinence • **EPIDEMIOLOGY AND IMPACT** Urinary incontinence is curable or controllable in many geriatric patients, especially those who have adequate mobility and mental functioning. Even when it is not curable, incontinence can be managed in a manner that keeps people comfortable, makes life easier for caregivers, and minimizes the costs of caring for the condition and its complications. Approximately one in three women and 15 to 20% of men aged >65 years have some degree of urinary incontinence. Between 5 and 10% of community-dwelling older adults have incontinence more often than weekly and/or use a pad for protection from urinary accidents. The prevalence is as high as 60–80% in many nursing homes, where residents often have both urinary and stool incontinence. Many older people (~40%) suffer from "overactive bladder," which may or may not include symptoms of incontinence. Symptoms of overactive bladder include urinary urgency (with or without incontinence), urinary frequency (voiding every two hours or more often), and nocturia (awakening at night to void). If nocturia alone is the predominant symptom, the patient should be asked about sleep disorders (see section that follows). The pathophysiology, evaluation, and management of overactive bladder are essentially the same as for urge urinary incontinence.

Incontinence is associated with social isolation and depression, and can be a precipitating factor in the decision to seek nursing home care when it cannot be managed in a manner that maintains hygiene and safety. In addition to predisposing to skin irritation and pressure ulcers, the most important potential complication of urinary incontinence and overactive bladder are falls and resultant injuries related to rushing to get to a toilet. Older people with gait disorders, especially those who have multiple episodes of nocturia or nocturnal incontinence, are at especially high risk for injuries. In addition to the bother of the condition to the older person or a caregiver, fall risk is a compelling reason for undertaking a diagnostic evaluation and specific treatment for incontinence and overactive bladder in the geriatric population.

TABLE 464-11 Key Principles in the Management of Dementia

Optimize the patient's physical and mental function through physical activity and mind plasticity principles and activities
Treatment underlying medical and other conditions (e.g., hypertension, Parkinson disease, depression
Avoid use of drugs with central nervous system side effects unless required for management of psychological or behavioral disturbances
Assess the environment and suggest alterations, if necessary
Encourage physical and mental activity
Avoid situations stressing intellectual capabilities; use memory aids whenever possible
Prepare the patient for changes in location
Emphasize good nutrition
Identify and manage behavioral symptoms and complications
Driving (consider a formal driving evaluation)
Wandering
Dangerous driving
Behavioral disorders
Depression
Agitation or aggressiveness
Psychosis (delusions, hallucinations)
Malnutrition
Incontinence
Provide ongoing care
Reassessment of cognitive and physical function
Treatment of medical conditions
Provide information to patient and family
Nature of the disease
Extent of impairment
Prognosis
Provide social service information to patient and family
Local Alzheimer's Association
Community health-care resources (day centers, homemakers, home health aides)
Legal and financial counseling
Use of advance directives
Provide family counseling for:
Setting realistic goals and expectations
Identification and resolution of family conflicts
Handling anger and guilt
Decisions on respite or institutional care
Legal concerns
Ethical concerns
Consideration of palliative and hospice care
Protect the caregiver from effects of caregiver stress

Source: Adapted from RL Kane et al: *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

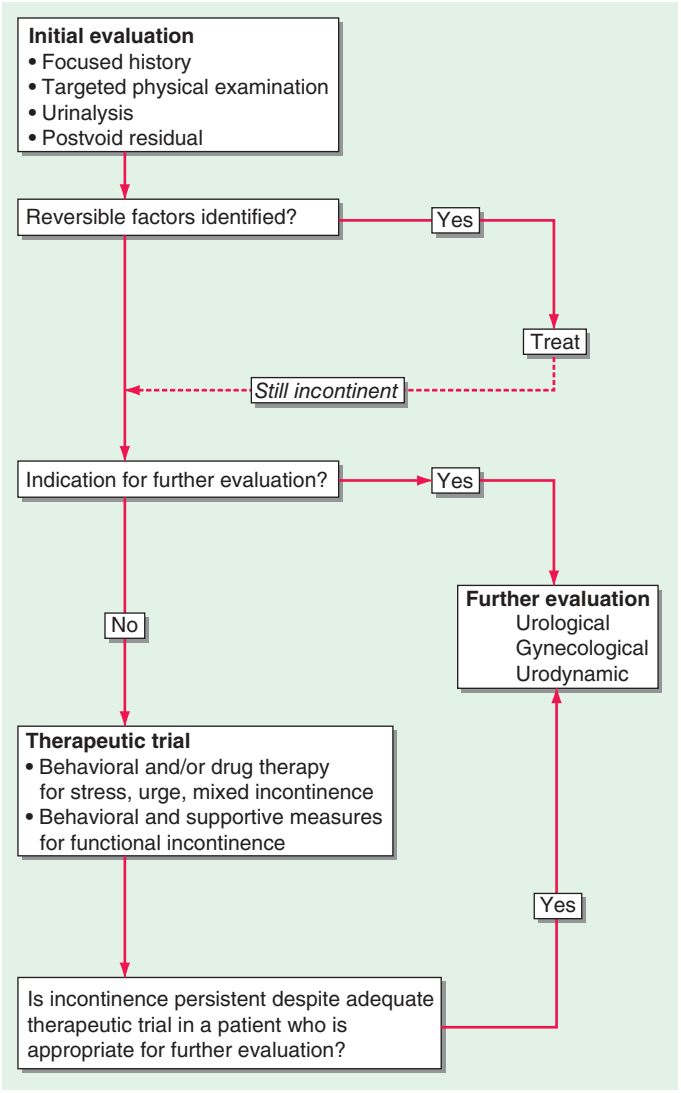

FIGURE 464-8 Algorithm for the basic evaluation and management of geriatric urinary incontinence in outpatient practice. *(Adapted from RL Kane et al: Essentials of Clinical Geriatrics, 8th ed. New York, McGraw-Hill, 2018.)*

EVALUATION Internists should ask older people about symptoms of urinary incontinence because these symptoms are often hidden out of embarrassment or fear. Simple questions can help identify incontinent patients, such as: "Do you have trouble with your bladder?" "Do you ever lose urine when you don't want to?" "Do you ever wear padding to protect yourself in case you lose urine?" (Table 464-3). A substantial number of older people will respond "no" to the first two questions, but "yes" to the third one.

Figure 464-8 illustrates an overall approach to the evaluation of the older patient with symptoms of incontinence and overactive bladder. The history and physical examination should focus on identifying potentially reversible causes and contributing factors (Table 464-12) and identifying the specific lower urinary tract symptoms. A simple, 3-item validated questionnaire can assist in distinguishing between the most common types of incontinence (Fig. 464-9). Among older women, the most common symptoms are a mixture of urge and stress incontinence (Fig. 464-10); urge is usually the more bothersome. Stress incontinence can often be objectively observed during a physical examination with a comfortably full bladder by having the patient cough in the standing position; leakage of urine simultaneously with coughing indicates that stress incontinence is present. Older men commonly have symptoms associated with overactive bladder and/or symptoms of voiding difficulty (hesitancy, poor or intermittent urinary stream, post-void dribbling); the overactive bladder symptoms are usually more bothersome. These symptoms overlap with those of both benign and malignant disorders of the prostate, and many internists may choose to consult a urologist for further management (see Chap. 83) because a urinary flow rate and post-void residual determination (PVR), and further evaluation if malignancy is suspected, are helpful in determining therapy.

Most older patients with symptoms of incontinence should have a PVR, especially men, diabetics, those with neurological disorders, and those with symptoms of voiding difficulty, because incomplete bladder emptying is common in older patients and is difficult to detect by history and physical examination alone. There is no specific cutoff for an abnormal PVR; the test must be done with a full bladder and straining during the test can alter the results. In older patients, a PVR between 0 and 100 mL is normal, between 100 and 200 mL must be interpreted based on symptoms, and a PVR higher than 200 is abnormal and usually influences treatment.

MANAGEMENT Patients who meet certain criteria should be referred for further urological, gynecological, and/or urodynamic evaluation

TABLE 464-12 Reversible Conditions That Cause or Contribute to Urinary Incontinence and Overactive Bladder Symptoms in Older People

CONDITION	MANAGEMENT
Lower urinary tract conditions	
Urinary tract infection (symptomatic with frequency, urgency, dysuria, etc.)	Antimicrobial therapy
Atrophic vaginitis/urethritis	Topical estrogen (not a primary treatment for incontinence but may help prevent recurrent infections and ameliorate symptoms of overactive bladder; oral estrogens can cause or worsen incontinence)
Stool impaction with irritation of bladder/urethral innervation and/or partial bladder outlet obstruction	Dis-impaction; appropriate use of stool softeners, bulk-forming agents, and laxatives if necessary; implement
Increased urine production	
Metabolic (hyperglycemia, hypercalcemia)	Better control of diabetes mellitus
	Therapy for hypercalcemia depends on underlying cause
Excess caffeine or fluid intake	Reduction in intake caffeinated beverages; reduction in fluid intake (most older people with incontinence or overactive bladder self-restrict fluid intake)
Volume overload with increased urine production at night	Support stockings
Venous insufficiency with edema	Leg elevation
	Sodium restriction
	Diuretic therapy (late afternoon dose may be effective)
Congestive heart failure	Medical therapy
Impaired ability or willingness to reach a toilet	
Delirium	Diagnosis and treatment of underlying cause(s)
Chronic illness, injury, or restraint that interferes with mobility	Regular toileting
	Use of toilet substitutes
	Environmental alterations (eg, bedside commode, urinal)
	Remove restraints if possible
Psychological (depression, anxiety)	Appropriate non-pharmacologic and/or pharmacologic treatment
Drug Side Effects	Remove offending drug(s) if feasible; modification of dose, frequency or timing may also reduce symptoms for some drugs:
	Diuretics (polyuria, frequency, urgency)
	Anticholinergics (constipation, incomplete bladder emptying)
	Psychotropic drugs
	Tricyclic antidepressants (anticholinergic effects)
	Antipsychotics (immobility, sedation)
	Sedative-hypnotics (immobility, sedation)
	Narcotic analgesics (constipation, incomplete bladder emptying)
	Alpha-Adrenergic blockers (urethral relaxation)
	Alpha-Adrenergic agonists (urethral contraction and potential incomplete bladder emptying)
	Cholinesterase inhibitors (urinary frequency, urgency)
	Angiotensin-converting enzyme inhibitors (cough precipitating stress incontinence)
	Calcium channel blockers, gabapentin, pregabalin, glitazones (edema with nocturia)
	Alcohol (polyuria, frequency, urgency, sedation, delirium, immobility)
	Caffeine (polyuria, bladder irritation)

Source: Adapted from RL Kane et al: *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

before initiating specific therapy. Examples include history of lower urinary tract surgery or radiation or recurrent symptomatic urinary tract infections, marked pelvic prolapse on physical examination of a woman, suspected prostate cancer, and sterile hematuria.

Potentially reversible conditions should be addressed, including the many types of medications that can affect bladder function, which should be eliminated if possible (Table 464-12). Table 464-13 lists treatments for different types of incontinence. Many patients respond well to properly taught and adhered to behavioral interventions. Physical therapists and nurses who specialize in treating lower urinary tract symptoms can be very helpful and should be consulted if available. Pharmacologic treatment of incontinence and overactive bladder is dictated by the innervation of the lower urinary tract. Alpha-adrenergic stimulation increases tone in the smooth muscle of the urethra, thus alpha agonists have been used to treat stress incontinence in women, and alpha blocker are used to decrease urethral tone in men with overactive bladder associated with prostate enlargement. Anticholinergic/antimuscarinic agents and beta-3 stimulation inhibit bladder contraction and are used for overactive bladder and urge incontinence. Patients with severe cognitive impairment and/or immobility can generally be managed effectively by prompted voiding and/or incontinence undergarments, as long comfort, dignity, and safety are maintained.

Sleep Disorders Sleep disorders are discussed in more detail for the general adult population in Chap. 27. Because they are so common and have some unique features in older patients, they are discussed briefly here.

EPIDEMIOLOGY AND IMPACT Aging is associated with multiple changes in sleep architecture as well as multiple diseases and disorders that can disrupt sleep. Thus, complaints of sleep difficulty are common in older adults. Consequences of sleep difficulty include lower health-related quality of life, increased medication use, more cognitive decline, and greater health care utilization. Four types of primary sleep disorders are common in the geriatric population: insomnia, sleep disordered breathing due to obstructive sleep apnea (OSA), restless leg syndrome (RLS), periodic leg movements in sleep (PLMS). Complaints of bothersome insomnia—the inability to fall asleep or stay asleep despite a conducive environment—increase with age and occur in ~30% of people aged >65. Insomnia is commonly associated with depression, anxiety, alcohol

The 3IQ is a patient questionaire that helps your doctor distinguish urge incontinence from stress incontinence. It should take no more than a couple of minutes. Complete the quiz and bring it to your next appointment.

1. During the last 3 months, have you leaked urine (even a small amount)?

☐ **Yes** ☐ **No** (if this response is marked, the 3IQ test is complete)

2. During the last 3 months, did you leak urine (check all that apply):

☐ When you were performing some physical activity, such as coughing, sneezing, litting, or exercising?

☐ When you had the urge or the feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?

☐ Without physical activity and without sense of urgency?

3. During the last 3 months, did you leak urine most often (check only one):

☐ When you were performing some physical activity, such as coughing, sneezing, litting, or exercising?

☐ When you had the urge or the feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?

☐ Without physical activity and without sense of urgency?

☐ About equally as often with physical activity as with a sense of urgency?

Definitions of type of urinary incontinence are based on responses to question 3.

Response to Question 3	Type of incontinence
Most often with physical activity	Stress only or stress predominant
Most often with the urge to empty the bladder	Urge only or urge predominant
Without physical activity or sense of urgency	Other cause only or other cause predominant
About equally with physical activity and sense of urgency	Mixed

FIGURE 464-9 The 3 Incontinence Questions (3IQ) Assessment Tool. *(From JS Brown et al: The sensitivity and specificity of a simple test to distinguish between urge and stress urinary incontinence. Ann Intern Med 144:715, 2006.)*

intake, and ingestion of caffeinated beverages later in the day. OSA occurs in ~10% of older adults, but is probably under-reported and under-diagnosed. It is associated with medical comorbidities, such as obesity and congestive heart failure. RLS occurs in 5–10% of adults, and its prevalence increases in those aged >70. It is almost twice as common in women than men; family history, iron deficiency, and intake of antihistamines and most antidepressants are risk factors. PLMS can be found in up to 45% of older people, but is often of unknown clinical consequence and remains undiagnosed.

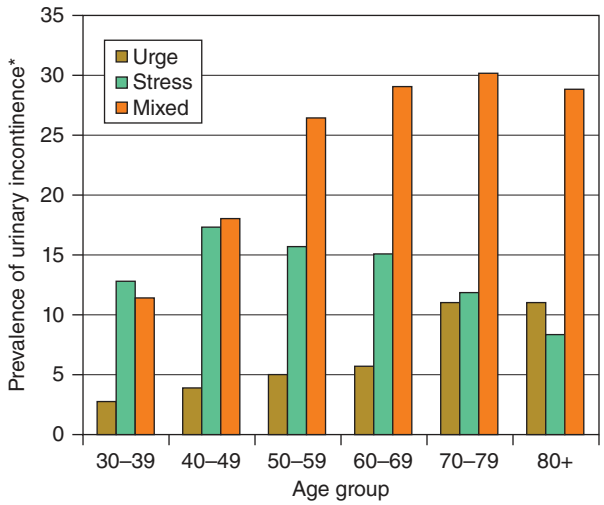

FIGURE 464-10 Rates of urge, stress, and mixed incontinence, by age group, in a sample of 3552 women. *Based on a sample of 3553 participants. *(From JL Melville et al: Arch Intern Med 165:537, 2005.)*

EVALUATION Older people should be screened for sleep difficulty with questions such as: "Do you often feel sleepy during the day?" "Do you have difficulty falling asleep at night?" Further evaluation of the nature and impact of the complaints can be accomplished with standardized questionnaires (Table 464-3). Patients with significant sleep complaints should be asked about conditions that can interrupt sleep, such as nocturia, gastroesophageal reflux, chronic pain, and caffeine and alcohol intake. Specific questions characterizing the complaints should include inquiring about loud snoring (for OSA), the urge to move legs associated with uncomfortable sensations (RLS), and leg movements during sleep (PLMS; which may result in kicking a bed partner).

MANAGEMENT Patients suspected for OSA, RLS, or PLMS should be referred for formal sleep evaluation. While hypnotics are among the most commonly prescribed drugs in the geriatric population, non-pharmacologic management of sleep should be the initial and primary approach, as many patients can benefit from properly taught and adhered to interventions (Table 464-14). Benzodiazepine hypnotics should be avoided whenever feasible because they are associated with next-day hangover effects, which may manifest as cognitive impairment and can precipitate falls and car crashes; and rebound insomnia.

Elder Abuse and Neglect • EPIDEMIOLOGY AND IMPACT

The incidence of elder abuse and neglect, and self-neglect are unknown

TABLE 464-13 Primary Treatments for Different Types of Geriatric Urinary Incontinence

TYPE OF INCONTINENCE	PRIMARY TREATMENTS
Stress	Pelvic muscle (Kegel) exercises Other behavioral interventions including timed voiding and double voiding to avoid residual urine α-Adrenergic agonist (none are FDA approved for this purpose) Topical estrogen to strengthen periurethral tissue (not effective alone; oral estrogens contraindicated) Periurethral injections to provide bulking and support Surgical bladder neck suspension or sling for severe incontinence, based on patient preference
Urge and overactive bladder symptoms	Pelvic muscle (Kegel) exercises Other behavioral interventions—timed voiding and double voiding to avoid residual urine Antimuscarinic and beta-3 adrenergic drugs
Incontinence with incomplete bladder emptying	α-Adrenergic antagonists (men) Bladder training, double voiding Intermittent catheterization Indwelling catheterization in selected patients in whom risks and discomforts of urinary retention outweigh risks of a chronic indwelling catheter
Incontinence with impaired physical and/or cognitive function	Behavioral interventions (prompted voiding, habit training) Environmental manipulation including use of urinal or bedside commode, safe lit path to bathroom Incontinence undergarments and pads

Source: Adapted from RL Kane et al: *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

TABLE 464-14 Non-Pharmacologic Management of Insomnia in Older Adults

Sleep Hygiene Rules
Check effect of medication on sleep and wakefulness
Avoid caffeine, alcohol, and cigarettes after lunch
Limit liquids in the evening
Keep a regular bedtime–waketime schedule
Avoid naps or limit to 1 nap a day, no longer than 30 min
Spend time outdoors (without sunglasses), particularly in the late afternoon or early evening
Exercise—but limit exercise immediately before bedtime
Instructions for Stimulus-Control Therapy
Only go to bed when tired or sleepy
If unable to fall asleep within 20 min, get out of bed (and bedroom if possible); while out of bed, do something quiet and relaxing
Only return to bed when sleepy
If unable to fall asleep within 20 min, again get out of bed
Repeat these behaviors until able to fall asleep within a few minutes
Get up at the same time each morning (even if only a few hours of sleep)
Avoid naps

Source: Adapted from JB Halter et al (eds): *Hazzard's Geriatric Medicine and Gerontology*, 7th ed. New York, McGraw-Hill, 2017.

because it is often not asked about or reported. The best data suggest that the incidence over 12 months is at least 8–10%. Abuse and neglect can result in physical injuries and related pain, worsening of chronic medical conditions, dehydration and pressure ulcers, emotional distress, and loss of income and savings and related consequences.

EVALUATION Because abuse and neglect are so under-reported, may be unsuspected, and have such devastating consequences, older adults should be screened (in the absence of caregivers) with questions such as: "Do you ever feel unsafe where you live? "Has anyone ever threatened or hurt you?" "Has anyone been taking your money without your permission?" (Table 464-3). Table 464-15 outlines the definitions, symptoms and signs, and key aspects of evaluating suspected abuse and neglect.

MANAGEMENT In addition to treating the physical, medical, and emotional consequences, patients suspected of elder abuse or neglect should be reported to the appropriate local or state agency to investigate and ensure the patient's safety. The reader is referred to two reviews of this topic for further information on specific aspects of management.

TABLE 464-15 Elder Abuse and Neglect

CATEGORY	DEFINITION AND EXAMPLES	SYMPTOMS AND SIGNS	KEY ASPECTS OF EVALUATION
Physical Abuse	Acts of violence that may result in pain, injury, or impairment • Pushing, slapping, hitting, force-feeding • Improper positioning or use of restraints • Improper use of medications	Abrasions Lacerations Bruises Fractures Use of restraints Burns Pain Depression Delirium or onset or worsening of dementia-related behavioral symptoms	The interview should be conducted alone with the patient; it may reveal discordant histories or findings inconsistent with the history provided by the caregiver. Ankles and wrists should be examined for abrasions suggestive of the use of restraints. Findings that are discordant with the mechanism of injury reported or multiple injuries in various stages of healing should raise the suspicion of abuse. Injuries to the head, neck, and upper arms occur in victims of physical elder abuse, but must be distinguished from accidental injuries. Jaw and zygomatic fractures are more likely to be sustained from a punch than from a fall, which more typically result in fractures to orbital and nasal bones.
Psychological or Verbal Abuse	Conduct that causes mental or emotional distress • Verbal harassment or intimidation • Threats of punishment or deprivation • Isolation	Direct observation of verbal abuse Subtle signs of intimidation, such as deferring questions to a caregiver or potential abuser Evidence of isolation Depression, anxiety, or both	Assess the size and quality of the patient's social network (beyond the suspected abuser). Conduct standardized assessments of depression, anxiety, and cognition, directly or through referral. Ask specifically about verbal or psychological abuse with questions such as "Does your relative/caregiver ever yell or curse at you?"; "Have you been threatened with being put into a nursing home?"; or "Are you ever prevented from seeing friends and family members whom you wish to see?"

(*Continued*)

TABLE 464-15 Elder Abuse and Neglect (Continued)

CATEGORY	DEFINITION AND EXAMPLES	SYMPTOMS AND SIGNS	KEY ASPECTS OF EVALUATION
Financial Abuse	Misuse of the person's income or resources for the financial or personal gain of a caregiver or advisor • Stealing money or possessions • Denying a home • Coercing to sign contracts or spend money	Inability to pay for medicine, medical care, food, rent, or other necessities Failure to renew prescriptions, adhere to medication regimens or other treatments, or keep medical appointments Malnutrition, weight loss, or both, without an obvious medical cause Evidence of poor financial decision making Firing of home care or other service providers by abuser Unpaid utility bills Initiation of eviction proceedings	Ask about financial exploitation with questions such as "Has money or property been taken from you without your consent?"; "Have your credit cards or automated-teller-machine card been used without your consent?"; and "At the end of the month, do you have enough money left for food and other necessities?" Abrupt changes in financial circumstances of the caregiver in either direction may herald an increased risk of financial exploitation or exploitation already under way. Abuse of the power of attorney; if the person with power of attorney or health care proxy is suspected of not acting in the best interest of the patient, documents necessary to ensure that the assumption of fiduciary responsibilities is authorized.
Sexual Abuse	Sexual coercion or assault	Bruising, abrasions, lacerations in the genital or anal areas or abdomen Newly acquired sexually transmitted diseases, especially in nursing home Urinary tract infection	Inquire directly about sexual assault or coercion. For patients with dementia, direct queries to caregivers about hypersexual behavior as part of a larger history regarding dementia-related behaviors and assess patient's capacity for decision-making about sexual activity If indicated, refer to an emergency department for assessment for sexual assault and collection of specimens (forensic evidence should be collected by experienced professionals, such as nurses who have undergone Sexual Assault Nurse Examiners (SANE) training.
Neglect (by caregiver or self-neglect)	Failure to provide the materials, supplies, food and drink or services necessary for optimal functioning or to avoid harm	Malnutrition Dehydration Poor hygiene Pressure ulcers Nonadherence to medication regimen or other treatments Worsening of dementia-related behavioral symptoms	Interview primary caregiver about his or her understanding of the nature of the patient's care needs and how well care is being rendered. Neglect by a caregiver may be intentional or unintentional Assess hygiene, cleanliness, and appropriateness of dress. Examine the skin for pressure ulcers, infections, and infestations. Assess nutrition and hydration, including measuring body-mass index And blood urea nitrogen and creatinine to assess hydration.

Source: Adapted from JB Halter et al (eds): *Hazzard's Geriatric Medicine and Gerontology*, 7th ed. New York, McGraw-Hill, 2017 and MS Lachs, KA Pillemer: Elder abuse. N Engl J Med 373:1947, 2015.

END-OF-LIFE AND PALLIATIVE CARE

As stated earlier, end-of-life and palliative care are critical aspects of caring for the geriatric population, and require a comprehensive, person-centered approach. End-of-life and palliative care are addressed in detail in Chap. 9, and pain management is addressed in Chap. 10. For geriatric patients, limited life expectancy is a critical factor to consider when making end-of-life care decisions. General principles of decision-making are especially relevant when considering palliative and/or end-of-life care in older patients (Fig. 464-4). Decision-making becomes complicated, however, among older patients with multimorbidity. Without a clear terminal diagnosis, when to start palliative care/end-of-life care could be challenging. While it is sometimes clear when an older patient has a terminal condition, such as end-stage congestive heart failure or chronic obstructive pulmonary disease, many older patients with multi-morbidity have combinations of conditions of varying severity. Moreover, neurogenerative disorders, including most forms of dementia, Parkinson's disease, and patients with multiple strokes commonly have a gradually progressive course, and it can be challenging to determine when discussions about palliative and end-of-life care should be initiated. Dementia, however, should be considered a terminal illness in the advanced stages.

Internists should play a pivotal role in making the decision when to initiate these discussions, and should be proactive in encouraging patients and their families to execute advance directives before a health care crisis occurs. The survivability of cardiopulmonary resuscitation in hospitalized patients aged ≥65 is <20%; among the old-old with multimorbidity it is much lower. The survivability of cardiopulmonary resuscitation (CPR) in nursing home residents is almost zero, making it a futile intervention for most in this setting. Enteral feeding tubes should not be placed in patients with end-stage dementia (Table 464-2). Estimation of prognosis using tools such as ePrognosis and careful attention to other factors that contribute to person-centered care will assist internists in dealing with these challenging issues in geriatric care.

465 Approach to Medical Consultation

Jack Ende, Jeffrey Berns

Effective health care requires teams of generalists and specialists with complementary expertise. Many clinical conditions require the input of more than one clinical provider, either because the diagnosis and recommended treatment is uncertain or because a patient may have multiple diseases that may be best managed by involving multiple specialists.

To *consult* is to seek advice from someone with expertise in a particular area, whereas *consultation* refers to the meeting or comparable outcome arising from that request. Medical consultation takes several forms. Its most traditional forms include in-hospital consultation in which physicians provide recommendations or perform procedures for a hospitalized patient, and out-patient consultations, in which patients are seen in the office setting. More contemporary forms of consultation include e-consultations, telemedicine evaluations (see "Consultation Involving Telemedicine," below), and remote medical second opinions. In these forms, the consultant may not actually see the patient but, nonetheless, assumes the responsibility of evaluating the patient's clinical condition, assessing and analyzing pertinent clinical data, and offering a synthesis and appropriate recommendations.

While forms of medical consultation evolve, basic responsibilities associated with medical consultation endure. These responsibilities can be divided into those that fall to the requesting physician or nonphysician practitioner; the consultant, who provides the consultation; and the health system, hospital, or organization that must support this important medical encounter **(Table 465-1)**.

TABLE 465-1 Stakeholder Responsibilities in the Medical Consultation Process

REFERRING PHYSICIAN OR PROVIDER	CONSULTANT PHYSICIAN	HEALTH SYSTEM, HOSPITAL, OR CARE ORGANIZATION
• Ensure patient participation and engagement • Be specific regarding clinical question and desired outcome • Communicate level of urgency • Avoid consulting for nonclinical purposes	• Maintain standards of professionalism, including those pertaining to availability, communication, respect, and collegiality • Appreciate levels of urgency and respond appropriately • Assemble and develop one's own database • Be specific in synthesis and recommendations • Understand desired outcomes, including arrangements for follow-up • Communicate with referring provider in whatever manner is mutually desirable	• Maintain adequate specialty workforce to enable appropriate access • Support systems for efficient exchange of clinical information • Develop culture of collegiality and team-based care

RESPONSIBILITIES OF THE REQUESTING PRACTITIONER

Before requesting a consultation, the provider should ensure that the patient endorses the purpose of the consultation, understands the role of the consultant, and anticipates the likely outcomes of the encounter. Further responsibilities of the requesting practitioner include being specific and communicating clearly the reason for the consultation. Vague messages such as, "Please evaluate" are not as helpful as more specific inquiries such as, "What is the cause of the declining kidney function?" or, "How should this asymptomatic pulmonary nodule be evaluated?" To the extent possible, the requesting practitioner should provide the relevant clinical information, summarized as succinctly as possible. Urgency should be clearly conveyed, typically with a phone call or other direct communication.

The requesting practitioner should be explicit regarding the intended outcome of the consultation, i.e., is this for a single evaluation or ongoing co-management? Communication between the requesting and the consulting providers is paramount. Whether this communication includes direct contact is less important than that the relevant information and desired outcome be explicit and clear, regardless of communication medium. Consultations should be requested for clinical purposes and always directed to qualified consultants; they should not be driven by entrepreneurial or relationship-building purposes. Another responsibility of the referring provider is not to "overconsult." Medical care should be focused on value, not volume.

RESPONSIBILITIES OF THE CONSULTANT

Just as the referring provider should attend to clear and explicit communication, so too should the consultant follow the precepts of effective interactions between professionals, which include courtesy, availability, and clarity. Particularly on the inpatient service, where consultants may receive several requests each day, it is important that the incoming consultations are triaged and dispatched as clinically appropriate. Consultants also need to determine the requested level of involvement going forward and not assume that long-term co-management is being sought. While consultants can and should make use of available clinical data, they should also assemble independently their own database, including taking a history, performing a physical exam, and reviewing pertinent clinical studies. Absent that, they may be unable to provide an independent and actionable synthesis. Just as the referring provider needs to be clear and concise, so too should the consultant be specific and focused in the recommendations provided. "Possible malignant ascites" is less helpful than, "I will arrange for paracentesis to exclude the possibility of malignant ascites." For the most part, recommendations to "consider" some diagnosis or test are less helpful than more specific and concrete advice. Some referring practitioners wish to be called after a patient is seen; others prefer that communication be handled as part of the medical record. How this communication is handled must also align with the complexity and urgency of the consultation and clinical circumstances.

RESPONSIBILITIES OF HEALTH SYSTEMS, HOSPITALS, AND MEDICAL ORGANIZATIONS

Health systems, hospitals, and medical organizations also have responsibilities in the consultation process. This responsibility includes ensuring that qualified consultants are accessible and available on the medical staff. Consultations within a single system are aided by common shared electronic medical records, particularly when consultations originate in the hospital, but can also involve care in the outpatient setting. Finally, health care entities should strive to foster a culture of team-based care and collegiality.

SPECIAL ISSUES IN MEDICAL CONSULTATION

Curbside Consults Curbside consults are requests from one practitioner to another for an informal and unwritten opinion about a

specific patient care matter. They are typically limited in scope, mostly regarding management or questions regarding procedures, and developed from information provided by the consulting practitioner and perhaps the medical record (such as labs and imaging studies), but without a comprehensive review of the record or any direct contact with the patient. Although often viewed as convenient, efficient, and a common aspect of clinical care, by their very nature, curbside consults have been found to often be incomplete or even flawed. It is not uncommon for the question being asked to be deemed too complex for a curbside consult, or for it not to be the actual or only issue the consultant feels needs to be addressed. As a general rule, curbside consults should be avoided. While medicolegal liability is often cited as a reason to limit curbside consults, the risk is actually negligible as U.S. courts have ruled that curbside consults do not establish a doctor-patient relationship necessary for creating the basis for medical malpractice litigation. An important exception, however, is when a curbside consult is provided by a resident or fellow in training; in this circumstance the trainee's supervising physician, whether aware of the curbside consult or not, is responsible for the recommendations of the trainee.

Second Opinions Physicians may find themselves providing consultations requested by patients who have already been evaluated for the same problem by another physician. Not a "consult" in the usual context of one physician referring a patient to another, the service provided by the consultant here is, nonetheless, very much aligned with a physician-referred consult. Second opinions, which often are encouraged by the patient's physician, may be sought by patients for reassurance that a diagnosis and treatment recommendation is correct, out of dissatisfaction with the initial physician, or with the hope of an entirely different opinion and recommendation. The physician providing the second opinion should strive to understand the patient's motivations for seeking the additional opinion. While a second opinion may have been initiated by the patient rather than referral from another physician, it is recommended that the consulting physician communicate with the patient's primary physician or specialist as would be done following a standard consultation unless the patient insists otherwise. In addition, professional behavior in how the consulting physician refers to the recommendations or actions of previously consulted physicians is important, even when there is disagreement. Likewise, it is important that a transfer of care from prior consultants to the one providing a second opinion be enacted only if specifically requested by the patient or the physician who encouraged the second opinion.

Consults Involving Mid-Level Providers Increasingly, specialist physicians may find themselves being consulted by nurse practitioners and physician assistants rather than other physicians. Whether the quality of the information provided to the consultant physician by a mid-level provider is different from physician-to-physician referrals has not been studied. Consulting physicians should know whether they should respond back to the mid-level provider or to the supervising physician. As with physician-to-physician consults, it is also important for the consultant to know whether the individual calling for the consult has an ongoing role in the care of the patient or is simply covering for a limited period of time. Finally, the consultant, if responding back to the mid-level provider, should make sure that the information provided meets the needs of that provider, and that questions are answered as they would be if responding back to another physician.

Consultation Involving Telemedicine Consultations making use of electronic health records, patient portals, and various forms of telecommunication technology, including video conferencing or cell phone communication, can improve access to care, reduce cost, and improve outcomes. This is particularly true when employed in geographic areas of health care shortage and when the clinical issues can be handled without direct contact with the patient, e.g., radiology or dermatology. However, the absence of direct contact between patient and consultant introduces special issues related to diagnostic accuracy and physician-patient relationship. Regulatory issues, liability, security, and confidentiality issues arise as well. Consultation via telemedicine holds considerable promise, but the aforementioned concerns will need to be better understood.

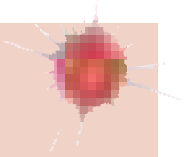
466 Medical Disorders During Pregnancy



Robert L. Barbieri, John T. Repke

Each year, approximately 4 million births occur in the United States, and more than 130 million births occur worldwide. A significant proportion of births are complicated by medical disorders. Advances in medical care and fertility treatment have increased the number of women with serious medical problems who attempt to become pregnant. Medical problems that interfere with the physiologic adaptations of pregnancy increase the risk for poor pregnancy outcome; conversely, in some instances, pregnancy may adversely impact an underlying medical disorder.

HYPERTENSION

(See also Chap. 271) In pregnancy, cardiac output increases by 40%, with most of the increase due to an increase in stroke volume. Heart rate increases by ~10 beats/min during the third trimester. In the second trimester, systemic vascular resistance decreases, and this decline is associated with a fall in blood pressure. During pregnancy, a blood pressure of 140/90 mmHg is considered to be abnormally elevated and is associated with an increase in perinatal morbidity and mortality. In all pregnant women, the measurement of blood pressure should be performed in the sitting position, because the lateral recumbent position may result in a lower blood pressure. The diagnosis of hypertension requires the measurement of two elevated blood pressures at least 4 h apart. Hypertension during pregnancy is usually caused by preeclampsia, chronic hypertension, gestational hypertension, or renal disease.

PREECLAMPSIA

Approximately 5–7% of all pregnant women develop *preeclampsia*, the new onset of hypertension (blood pressure >140/90 mmHg) and proteinuria (either a 24 h urinary protein >300 mg/24 h, or a protein-creatinine ratio ≥0.3) after 20 weeks of gestation. Recent revisions to the diagnostic criteria include: proteinuria is no longer an absolute requirement for making the diagnosis; the terms mild and severe preeclampsia have been replaced; and the disease is now termed preeclampsia either with or without severe features and fetal growth restriction is no longer a defining criterion for preeclampsia with severe features. Although the precise pathophysiology of preeclampsia remains unknown, recent studies show excessive placental production of antagonists to both vascular endothelial growth factor (VEGF) and transforming growth factor β (TGF-β). These antagonists to VEGF and TGF-β disrupt endothelial and renal glomerular function resulting in edema, hypertension, and proteinuria. The renal histological feature of preeclampsia is glomerular endotheliosis. Glomerular endothelial cells are swollen and encroach on the vascular lumen. Preeclampsia is associated with abnormalities of cerebral circulatory autoregulation, which increase the risk of stroke at mildly and moderately elevated blood pressures. Risk factors for the development of preeclampsia include nulliparity, diabetes mellitus, a history of renal disease or chronic hypertension, a prior history of preeclampsia, extremes of maternal age (>35 years or <15 years), obesity, antiphospholipid antibody syndrome, and multiple gestation. Low-dose aspirin (81 mg daily, initiated at the end of the first trimester) modestly reduces the risk of preeclampsia in pregnant women at high risk of developing the disease.

Preeclampsia with severe features is the presence of new-onset hypertension and proteinuria accompanied by end-organ damage. Features may include severe elevation of blood pressure (>160/110 mmHg), evidence of central nervous system (CNS) dysfunction (headaches, blurred vision, seizures, coma), renal dysfunction (oliguria or creatinine >1.5 mg/dL), pulmonary edema, hepatocellular injury (serum alanine aminotransferase level more than twofold the upper limit of normal), hematologic dysfunction (platelet count <100,000/L or disseminated intravascular coagulation [DIC]). The *HELLP syndrome* (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) is a special subtype of severe preeclampsia and is a major cause of morbidity and mortality in this disease. Platelet dysfunction and coagulation disorders further increase the risk of stroke.

TREATMENT

Preeclampsia

Preeclampsia resolves within a few weeks after delivery. For pregnant women with preeclampsia prior to 37 weeks of gestation, delivery reduces the mother's morbidity but exposes the fetus to the risk of premature birth. The management of preeclampsia is challenging because it requires the clinician to balance the health of the mother and fetus simultaneously. In general, prior to term, women with preeclampsia without severe features may be managed conservatively with limited physical activity, although bed rest is not recommended, close monitoring of blood pressure and renal function, and careful fetal surveillance. For women with preeclampsia with severe features, delivery is recommended unless the patient is eligible for expectant management in a tertiary hospital setting. Expectant management of preeclampsia with severe features remote from term affords some benefits for the fetus, but significant risks for the mother. Postponing delivery beyond 34 weeks gestation in this group of patients is not recommended. In preeclampsia without severe features delivery at 37 weeks is recommended.

The definitive treatment of preeclampsia is delivery of the fetus and placenta. For women with preeclampsia with severe features, aggressive management of blood pressures >160/105 mmHg reduces the risk of cerebrovascular accidents. IV labetalol or hydralazine is most commonly used to acutely manage severe hypertension in preeclampsia; labetalol is associated with fewer episodes of maternal hypotension. Elevated arterial pressure should be reduced slowly to avoid hypotension and a decrease in blood flow to the fetus.

Magnesium sulfate is the preferred agent for the prevention and treatment of eclamptic seizures. Large, randomized clinical trials have demonstrated the superiority of magnesium sulfate over phenytoin and diazepam in reducing the risk of seizure and, possibly, the risk of maternal death. Magnesium may prevent seizures by interacting with *N*-methyl-D-aspartate (NMDA) receptors in the CNS. The universal use of magnesium sulfate for seizure prophylaxis in preeclampsia without severe features is no longer recommended by most experts. There is consensus that magnesium sulfate should be used in all cases of preeclampsia with severe features, or in cases of eclampsia. Women who have had preeclampsia appear to be at increased risk of cardiovascular and renal disease later in life.

CHRONIC ESSENTIAL HYPERTENSION

Pregnancy complicated by chronic essential hypertension is associated with intrauterine growth restriction and increased perinatal mortality. Pregnant women with chronic hypertension are at increased risk for superimposed preeclampsia and abruptio placentae. Women with chronic hypertension should have a thorough prepregnancy evaluation, both to identify remediable causes of hypertension and to ensure that the prescribed antihypertensive agents (e.g., angiotensin-converting enzyme [ACE] inhibitors, angiotensin-receptor blockers) are not associated with an adverse outcome of pregnancy. Labetalol and nifedipine are the most commonly used medications for the treatment of chronic hypertension in pregnancy. The target blood pressure is in the range of 130–150 mmHg systolic and 80–100 mmHg diastolic. Should hypertension worsen during pregnancy, baseline evaluation of renal function (see below) is necessary to help differentiate the effects of chronic hypertension from those of superimposed preeclampsia. There are no convincing data that the treatment of mild chronic hypertension improves perinatal outcome.

GESTATIONAL HYPERTENSION

The development of elevated blood pressure after 20 weeks of pregnancy or in the first 24 h post-partum in the absence of preexisting chronic hypertension or proteinuria is referred to as *gestational hypertension*. Mild gestational hypertension that does not progress to preeclampsia has not been associated with adverse pregnancy outcome or adverse long-term prognosis.

RENAL DISEASE

Normal pregnancy is characterized by an increase in glomerular filtration rate and creatinine clearance. This increase occurs secondary to a rise in renal plasma flow and increased glomerular filtration pressures. Patients with underlying renal disease and hypertension may expect a worsening of hypertension during pregnancy. If superimposed preeclampsia develops, the additional endothelial injury results in a capillary leak syndrome that may make management challenging. In general, patients with underlying renal disease and hypertension benefit from aggressive management of blood pressure. Preconception counseling is also essential for these patients so that accurate risk assessment and medication changes can occur prior to pregnancy. In general, a prepregnancy serum creatinine level <133 μmol/L (<1.5 mg/dL) is associated with a favorable prognosis. When renal disease worsens during pregnancy, close collaboration between the internist and the maternal-fetal medicine specialist is essential so that decisions regarding delivery can be weighed to balance the sequelae of prematurity for the neonate versus long-term sequelae for the mother with respect to future renal function.

CARDIAC DISEASE

VALVULAR HEART DISEASE

(See also Chaps. 256–263) Valvular heart disease is the most common cardiac problem complicating pregnancy.

Mitral Stenosis This is the valvular disease most likely to cause death during pregnancy. The pregnancy-induced increase in blood volume, cardiac output, and tachycardia can increase the transmitral pressure gradient and cause pulmonary edema in women with mitral stenosis. Women with moderate to severe mitral stenosis (mitral valve area ≤1.5 cm^2) who are planning pregnancy and have either symptomatic disease or pulmonary hypertension should undergo valvuloplasty prior to conception, preferably with percutaneous balloon valvotomy (PBV). Pregnancy associated with long-standing mitral stenosis may result in pulmonary hypertension. Sudden death has been reported when hypovolemia occurs. Careful control of heart rate, especially during labor and delivery, minimizes the impact of tachycardia and reduced ventricular filling times on cardiac function. Pregnant women with mitral stenosis are at increased risk for the development of atrial fibrillation and other tachyarrhythmias. The immediate postpartum period is a time of particular concern secondary to rapid volume shifts. Careful monitoring of cardiac and fluid status should be observed.

Mitral Regurgitation and Aortic Regurgitation and Stenosis The pregnancy-induced decrease in systemic vascular resistance reduces the risk of cardiac failure with these conditions, especially in women with chronic lesions. Acute onset of mitral or aortic regurgitation may not be well tolerated during pregnancy. For women with severe aortic stenosis, treatment before pregnancy should be considered for a peak-to-peak valve gradient >50 mmHg. In women with aortic stenosis and a mean valve gradient <25 mmHg, pregnancy is likely to be well tolerated. For women with mitral or aortic regurgitation and left ventricular dysfunction (LVEF <30%) pregnancy should be avoided.

CONGENITAL HEART DISEASE

(See also Chap. 264) Reparative surgery has markedly increased the number of adult women with surgically repaired congenital heart disease. Maternal morbidity and mortality are greater among these women than among those without surgical cardiac repair. When pregnant, these patients should be jointly managed by a cardiologist and an obstetrician familiar with these problems. The presence of a congenital cardiac lesion in the mother increases the risk of congenital cardiac disease in the newborn. Prenatal screening of the fetus for congenital cardiac disease with ultrasound is recommended.

OTHER CARDIAC DISORDERS

Supraventricular tachycardia (Chap. 241) is a common cardiac complication of pregnancy. Treatment is the same as in the nonpregnant patient, and fetal tolerance of medications such as adenosine and calcium channel blockers is acceptable. When necessary, pharmacologic or electric cardioversion may be performed to improve cardiac performance and reduce symptoms. This intervention is generally well tolerated by mother and fetus.

Peripartum cardiomyopathy (Chap. 254) is an uncommon disorder of pregnancy and its etiology remains unknown. Approximately 10% of women with peripartum cardiomyopathy carry a truncating mutation in the gene encoding the titin sarcomere protein. Treatment is directed toward symptomatic relief and improvement of cardiac function. Many patients recover completely; others are left with progressive dilated cardiomyopathy. Recurrence in a subsequent pregnancy has been reported, and women who do not have normal baseline left-ventricular function after an episode of peripartum cardiomyopathy should be counseled to avoid pregnancy.

SPECIFIC HIGH-RISK CARDIAC LESIONS

Marfan Syndrome (See also Chap. 406) This autosomal dominant disease is associated with an increased risk of aortic dissection and rupture. An aortic root diameter <40 mm is associated with a favorable outcome of pregnancy; conversely, an aortic root diameter >40 mm is associated with an increased risk of aortic dissection. Prophylactic therapy with beta blockers has been advocated to reduce aortic dilation and the risk of dissection. A "cardiac delivery" with reduced pushing and early intervention with operative delivery is often recommended to reduce increases in aortic wall stress caused by the Valsalva maneuver.

Ehlers-Danlos syndrome (*EDS*) may be associated with premature labor, and in type IV EDS there is increased risk of organ or vascular rupture that may cause death. For women with vascular EDS, pregnancy is relatively contraindicated because of the high risk of vascular and uterine rupture.

Pulmonary Hypertension (See also Chap. 277) Maternal mortality in the setting of severe pulmonary hypertension is high, and primary pulmonary hypertension is a contraindication to pregnancy. Termination of pregnancy may be advisable in these circumstances to preserve the life of the mother. In the *Eisenmenger syndrome*, i.e., the combination of pulmonary hypertension with right-to-left shunting due to congenital abnormalities (Chap. 264), maternal and fetal deaths occur frequently. Systemic hypotension may occur after blood loss, prolonged Valsalva maneuver, or regional anesthesia; sudden death secondary to hypotension is a dreaded complication. Management of these patients is challenging, and invasive hemodynamic monitoring during labor and delivery is recommended in severe cases.

In patients with pulmonary hypertension, vaginal delivery is less stressful hemodynamically than cesarean section, which should be reserved for accepted obstetric indications.

DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM

(See also Chap. 273) Pregnancy is associated with venous stasis, endothelial injury and a hypercoagulable state. Inherited thrombophilias and the presence of antiphospholipid antibodies increase the risk of venous thromboembolism (VTE) in pregnancy. Deep venous thrombosis (DVT) or pulmonary embolism (PE) occurs in about 1 in 500 pregnancies, with DVT being three times more common than PE. VTE occurs more commonly in the 6 weeks post-partum than antepartum. In pregnant women, most unilateral DVTs occur in the left leg because the left iliac vein is compressed by the right iliac artery and the uterus compresses the inferior vena cava.

TREATMENT

Deep Venous Thrombosis

Aggressive diagnosis and management of DVT and suspected pulmonary embolism optimize the outcome for mother and fetus. In general, all diagnostic and therapeutic modalities afforded that the nonpregnant patient should be utilized in pregnancy except for D-dimer measurement, in which values are elevated in normal pregnancy. Anticoagulant therapy with low-molecular-weight heparin (LMWH) or unfractionated heparin is indicated in pregnant women with DVT. LMWH may be associated with an increased risk of epidural hematoma in women receiving an epidural anesthetic in labor and must be discontinued at least 24 h before placement of an epidural catheter. Warfarin therapy is contraindicated in the first trimester due to its association with fetal chondrodysplasia punctata. In the second and third trimesters, warfarin may cause fetal optic atrophy and mental retardation. In pregnancy the use of warfarin is restricted to women with mechanical heart valves. Warfarin is not contraindicated in breast-feeding women. For women at moderate or high risk of DVT who have a cesarean delivery, mechanical and/or pharmacologic prophylaxis is warranted.

ENDOCRINE DISORDERS

DIABETES MELLITUS

(See also Chaps. 396–398) In pregnancy, the fetoplacental unit induces major metabolic changes, the purpose of which is to shunt glucose and amino acids to the fetus while the mother uses ketones and triglycerides to fuel her metabolic needs. These metabolic changes are accompanied by maternal insulin resistance caused in part by placental production of steroids, a growth hormone variant, and placental lactogen. Although pregnancy has been referred to as a state of "accelerated starvation," it is better characterized as "accelerated ketosis." In pregnancy, after an overnight fast, plasma glucose is lower by 0.8–1.1 mmol/L (15–20 mg/dL) than in the nonpregnant state. This difference is due to the use of glucose by the fetus. In early pregnancy, fasting may result in circulating glucose concentrations in the range of 2.2 mmol/L (40 mg/dL) and may be associated with symptoms of hypoglycemia. In contrast to the decrease in maternal glucose concentration, plasma hydroxybutyrate and acetoacetate levels rise to two to four times normal after a fast.

TREATMENT

Diabetes Mellitus in Pregnancy

Pregnancy complicated by diabetes mellitus is associated with higher maternal and perinatal morbidity and mortality rates. Preconception counseling and treatment are important for the diabetic patient contemplating pregnancy and can reduce the risk of congenital malformations and improve pregnancy outcome. Folate supplementation reduces the incidence of fetal neural tube defects, which occur with greater frequency in fetuses of diabetic mothers. In addition, optimizing glucose control during key periods of organogenesis reduces other congenital anomalies, including sacral agenesis, caudal dysplasia, renal agenesis, and ventricular septal defect.

Once pregnancy is established, glucose control should be managed more aggressively than in the nonpregnant state. In addition to dietary changes, this enhanced management requires more frequent blood glucose monitoring and often involves additional injections of insulin or conversion to an insulin pump. Fasting blood glucose levels should be maintained at <5.8 mmol/L (<105 mg/dL), with avoidance of values >7.8 mmol/L (140 mg/dL). Sequential

measurement of hemoglobin A1c is of minimal value for monitoring glucose control during pregnancy because of the higher rate of red blood cell turnover during pregnancy. Commencing in the third trimester, regular surveillance of maternal glucose control as well as assessment of fetal growth (obstetric sonography) and fetoplacental oxygenation (fetal heart rate monitoring or biophysical profile) optimize pregnancy outcome. Pregnant diabetic patients without vascular disease are at greater risk for delivering a macrosomic fetus, and attention to fetal growth via clinical and ultrasound examination is important. Fetal macrosomia is associated with an increased risk of maternal and fetal birth trauma, including permanent injury to the brachial plexus. Pregnant women with diabetes have an increased risk of developing preeclampsia, and those with vascular disease are at greater risk for developing intrauterine growth restriction, which is associated with an increased risk of fetal and neonatal death. Excellent pregnancy outcomes in patients with diabetic nephropathy and proliferative retinopathy have been reported with aggressive glucose control and intensive maternal and fetal surveillance.

As pregnancy progresses, glycemic control may become more difficult to achieve due to an increase in insulin resistance. In pregnant women with Type 1 diabetes, closed-loop insulin delivery with both continuous interstitial glucose monitoring and sensor-augmented insulin pump therapy is helpful in normalizing circulating glucose with few episodes of hypoglycemia. In general, efforts to control glucose and avoid preterm delivery result in the best overall outcome for both mother and newborn. Preterm delivery is generally performed only for the usual obstetric indications (e.g., preeclampsia, fetal growth restriction, non-reassuring fetal testing) or for worsening maternal renal or active proliferative retinopathy.

GESTATIONAL DIABETES (GDM)

GDM occurs in ~4% of pregnancies. Because about 90% of women have at least one risk factor for GDM, all pregnant women should be screened for GDM. A typical two-step strategy for establishing the diagnosis of GDM is performed at 24–28 weeks of gestation and involves administration of a 50-g oral glucose challenge with a single serum glucose measurement at 60 min. If the plasma glucose is <7.8 mmol/L (<130 mg/dL) the test is considered normal. Plasma glucose >7.8 mmol/L (>130 mg/dL) warrants administration of a 100-g oral glucose challenge with plasma glucose measurements obtained in the fasting state and at 1, 2, and 3 h. Normal plasma glucose concentrations at these time points are <5.3 mmol/L (<95 mg/dL), <10 mmol/L (<180 mg/dL), <8.6 mmol/L (<155 mg/dL), and <7.8 mmol/L (<140 mg/dL) as the upper norms for a 3-h glucose tolerance test. Two elevated glucose values indicate a positive test. Adverse pregnancy outcomes for mother and fetus appear to increase with glucose as a continuous variable; thus it is challenging to define the optimal threshold for establishing the diagnosis of GDM.

Pregnant women with GDM are at increased risk of stillbirth, preeclampsia, and delivery of infants who are large for their gestational age, with resulting birth lacerations, shoulder dystocia, and birth trauma including brachial plexus injury. These fetuses are at risk of hypoglycemia, hyperbilirubinemia, and polycythemia. Tight control of blood sugar during pregnancy and labor can reduce these risks.

TREATMENT

Gestational Diabetes

Treatment of GDM with a two-step strategy—dietary intervention followed by insulin injections if diet alone does not adequately control blood sugar (fasting glucose <5.6 mmol/L [<100 mg/dL] and 2-h postprandial glucose <7.0 mmol/L [<126 mg/dL])—is associated with a decreased risk of birth trauma for the fetus. Oral hypoglycemic agents such as glyburide and metformin have become more commonly utilized for managing GDM refractory to nutritional management, but most experts favor insulin therapy. For women with GDM, there is a 40% risk of being diagnosed with diabetes within the 10 years after the index pregnancy. All women with GDM should have a formal glucose tolerance test (GTT) to screen for T2DM at ~6 weeks post-partum. In women with a history of GDM, exercise, weight loss, and treatment with metformin reduce the risk of developing diabetes. Lactation also reduces the risk of GDM progressing to T2DM. All women with a history of GDM should be counseled about prevention strategies and evaluated regularly for diabetes.

OBESITY

(See also Chap. 395) Pregnant women who are obese have an increased risk of stillbirth, congenital fetal malformations, GDM, preeclampsia, urinary tract infections, preterm and post-date delivery, and cesarean delivery. Women contemplating pregnancy should attempt to attain a healthy weight prior to conception. For morbidly obese women who have not been able to lose weight with lifestyle changes, bariatric surgery reduces the risks for GDM, macrosomia, and preterm delivery. Following bariatric surgery, women should delay conception for 1 year to avoid pregnancy during an interval of rapid metabolic changes. The National Academy of Medicine guidelines for weight gain during pregnancy recommend that for BMI ranges of <18.5, 18.5–24.9, 25.0–29.9, and ≥30 kg/m^2, weight gain targets should be 12.5–18 kg, 11.5–16 kg, 7–11.5 kg, and 5–9 kg, respectively.

THYROID DISEASE

(See also Chap. 375) In pregnancy, the estrogen-induced increase in thyroxine-binding globulin increases circulating levels of total T_3 and total T_4. Placental human chorionic gonadotropin (hCG) directly stimulates the thyroid causing an increase in free T_3 and T_4. Interpretation of the measurement of free T_4, free T_3, and thyroid-stimulating hormone (TSH) should use trimester-specific ranges.

TREATMENT

Hyperthyroidism in Pregnancy

HYPERTHYROIDISM

Methimazole crosses the placenta to a greater degree than propylthiouracil and has been associated with fetal aplasia cutis. However, propylthiouracil can be associated with liver failure. Some experts recommend propylthiouracil in the first trimester and methimazole thereafter. Radioiodine should not be used during pregnancy, either for scanning or for treatment, because of effects on the fetal thyroid. In emergent circumstances, additional treatment with beta blockers may be necessary. Hyperthyroidism is most difficult to control in the first trimester of pregnancy and easiest to control in the third trimester. In women with high-titer thyroid stimulating antibodies, the newborn may be born with neonatal Graves' disease.

HYPOTHYROIDISM

The goal of therapy for hypothyroidism is to maintain the serum TSH in the normal range, and thyroxine is the drug of choice. During pregnancy, the dose of thyroxine required to keep the TSH in the normal range rises. In one study, the mean replacement dose of thyroxine required to maintain the TSH in the normal range was 0.1 mg daily before pregnancy and increased to 0.15 mg daily during pregnancy. Since the increased thyroxine requirement occurs as early as the fifth week of pregnancy, one approach is to increase the thyroxine dose by 30% (two additional pills weekly) as soon as pregnancy is diagnosed and then adjust the dose by serial measurements of TSH.

HEMATOLOGIC DISORDERS

Pregnancy has been described as a state of physiologic anemia. Part of the reduction in hemoglobin concentration is dilutional, but iron and folate deficiencies are major causes of correctable anemia during pregnancy.

In populations at high risk for hemoglobinopathies **(Chap. 94)**, hemoglobin electrophoresis should be performed as part of the prenatal screen. Hemoglobinopathies can be associated with increased maternal and fetal morbidity and mortality. Management is tailored

to the specific hemoglobinopathy and is generally the same for both pregnant and nonpregnant women. Prenatal diagnosis of hemoglobinopathies in the fetus is readily available and should be discussed with prospective parents either prior to or early in pregnancy.

Thrombocytopenia occurs commonly during pregnancy. The majority of cases are benign gestational thrombocytopenias, but the differential diagnosis should include immune thrombocytopenia **(Chap. 111)**, preeclampsia, and thrombotic thrombocytopenic purpura. Benign gestational thrombocytopenia is unlikely if the platelet count is <100,000 per μL.

NEOPLASIA

Cancer complicates ~1 in every 1000 pregnancies. Of all the cancers that occur in women, <1% complicate pregnancies. The four cancers that occur most commonly in pregnancy are cervical cancer, breast cancer, melanoma, and lymphomas (particularly Hodgkin's lymphoma); however, virtually every form of cancer has been reported in pregnant women **(Table 466-1)**. In addition to cancers developing in other organs of the mother, gestational trophoblastic tumors can arise from the placenta.

Managing cancer in a pregnant woman is complex. One must take into account (1) the possible influence of the pregnancy on the natural history of the cancer, (2) effects on the mother and fetus of complications from the malignancy (e.g., anorexia, nausea, vomiting, malnutrition), (3) potential effects of diagnostic and staging procedures, and (4) potential effects of cancer treatments on both the mother and the developing fetus. Generally, the management that optimizes maternal physiology is also best for the fetus. The dilemma occasionally arises that what is best for the mother may be harmful to the fetus, and what is best for the fetus may compromise the ultimate prognosis for the mother. The best way to approach management of a pregnant woman with cancer is to ask, "What would one do in this clinical situation if she was not pregnant? Then, which, if any aspect of those plans need to be modified because she is pregnant?"

TREATMENT

Special Therapeutic Considerations in Pregnancy

Exposure of developing fetuses to ionizing radiation may cause adverse fetal effects; awareness of this potential toxicity has resulted in a disproportionate aversion to diagnostic imaging in pregnancy. The fetus is most sensitive to teratogenesis during organogenesis in the first trimester. Imaging that uses ionizing radiation should not be done without a compelling reason and due consideration to obtaining the necessary information by alternative imaging modalities. Exposure to diagnostic and therapeutic radionuclides, especially radioactive iodine, poses unique risks, but a full discussion of these is beyond the scope of this chapter.

Generally, toxic chemotherapy should be avoided during pregnancy, if at all possible. It should virtually never be given in the first trimester. A variety of single agents and combinations have been administered in the second and third trimesters, without a high frequency of toxic effects to the pregnancy or the fetus, but data on safety are sparse. A database on the risks associated with individual chemotherapy agents is available (*http://ntp.niehs.nih.gov/ntp/ohat/cancer_chemo_preg/chemopregnancy_monofinal_508.pdf*). If the malignancy is slowly progressive, and if the patient is near her delivery date, and if waiting until delivery to begin treatment is not anticipated to compromise maternal prognosis, then delaying treatment until after delivery to avoid fetal exposure to chemotherapy is desirable. If there is a greater sense of urgency to begin definitive treatment to avoid compromising maternal prognosis, and the patient is beyond 24 weeks of gestation but remote from her delivery date, then treatment (surgical, medical, or both) might be initiated during pregnancy and plans made to deliver the fetus early to avoid exposure to more chemotherapy than absolutely necessary. Since neonatal prognosis is most closely linked to gestational age at delivery, decisions regarding timing of delivery should include input from Maternal-Fetal Medicine, Neonatology, and Oncology. Finally, if the patient is in her first trimester and toxic chemotherapy must be initiated promptly to avoid a very poor maternal outcome, then it may be necessary to consider therapeutic abortion to avoid maternal disaster and fetal survival with injury resulting in long-term morbid sequelae. In general, pregnancy has relatively little or no impact on the natural history of malignancies, despite the hormonal influences. Spread of the mother's cancer to the fetus (so-called *vertical transmission*) is exceedingly rare.

TABLE 466-1 Incidence of Malignant Tumors During Gestation

TUMOR TYPE	INCIDENCE PER 10,000 PREGNANCIES[a]	% OF CASES[b]
Breast cancer	1–3	25%
Cervical cancer	1.2–4.5	25%
Thyroid cancer	1.2	15%
Hodgkin's disease	1.6	10%
Melanoma	1–2.6	8%
Ovarian cancer	0.8	2%
All sites	10	100%

[a]These are estimates based on extrapolations from a review of more than 3 million pregnancies (LH Smith et al: Am J Obstet Gynecol 184:1504, 2001).
[b]Based on accumulating case reports from the literature; the precision of these data is not high.

NEUROLOGIC DISORDERS

For women with epilepsy planning pregnancy, consideration should be given to switching from valproate, a known teratogen, to another medication. If valproate is continued during pregnancy, folic acid supplementation should be increased to 4 mg daily.

Patients with preexisting *multiple sclerosis* **(Chap. 436)** experience a gradual decrease in the risk of relapses as pregnancy progresses and, conversely, an increase in attack risk during the postpartum period. Disease-modifying agents, including interferon β, should *not* be administered to pregnant multiple sclerosis patients, but moderate or severe relapses can be safely treated with pulse glucocorticoid therapy. Finally, certain tumors, particularly pituitary adenoma and meningioma **(Chap. 373)**, may manifest during pregnancy because of accelerated growth, possibly driven by hormonal factors.

Peripheral nerve disorders associated with pregnancy include *Bell's palsy* (idiopathic facial paralysis) **(Chap. 438)**, which is approximately threefold more likely to occur during the third trimester and immediate postpartum period than in the general population. Therapy with glucocorticoids should follow the guidelines established for nonpregnant patients. Entrapment neuropathies are common in the later stages of pregnancy, presumably as a result of fluid retention. *Carpal tunnel syndrome* (median nerve) presents first as pain and paresthesia in the hand (often worse at night) and later with weakness in the thenar muscles. Treatment is generally conservative; wrist splints may be helpful, and glucocorticoid injections or surgical section of the carpal tunnel can usually be postponed. *Meralgia paresthetica* (lateral femoral cutaneous nerve entrapment) consists of pain and numbness in the lateral aspect of the thigh without weakness. Patients are usually reassured to learn that these symptoms are benign and can be expected to remit spontaneously after the pregnancy has been completed. *Restless leg syndrome* is the most common peripheral nerve and movement disorder in pregnancy. Disordered iron metabolism is the suspected etiology. Management is expectant in most cases.

GASTROINTESTINAL AND LIVER DISEASE

Up to 90% of pregnant women experience nausea and vomiting during the first trimester of pregnancy. *Hyperemesis gravidarum* is a severe form that prevents adequate fluid and nutritional intake and may require hospitalization to prevent dehydration and malnutrition.

Crohn's disease may be associated with exacerbations in the second and third trimesters. Ulcerative colitis is associated with disease exacerbations in the first trimester and during the early postpartum period.

Medical management of these diseases during pregnancy is similar to management in the nonpregnant state (Chap. 319).

Exacerbation of gallbladder disease is common during pregnancy. In part, this aggravation may be due to pregnancy-induced alteration in the metabolism of bile and fatty acids. Intrahepatic cholestasis of pregnancy is generally a third-trimester event. Profound pruritus may accompany this condition, and it may be associated with increased fetal mortality. Placental bile salt deposition may contribute to progressive uteroplacental insufficiency. Therefore, regular fetal surveillance should be undertaken once the diagnosis of intrahepatic cholestasis is made, and delivery should be planned once the fetus reaches about 37 weeks of gestation. Favorable results with ursodiol have been reported.

Acute fatty liver is a rare complication of pregnancy. Frequently confused with the HELLP syndrome (see "Preeclampsia" above) and severe preeclampsia, the diagnosis of acute fatty liver of pregnancy may be facilitated by imaging studies and laboratory evaluation. Acute fatty liver of pregnancy is generally characterized by markedly increased serum levels of bilirubin and ammonia and by hypoglycemia. Management of acute fatty liver of pregnancy is supportive; recurrence in subsequent pregnancies has been reported.

All pregnant women should be screened for hepatitis B. This information is important for pediatricians after delivery of the infant. All infants receive hepatitis B vaccine. Infants born to mothers who are carriers of hepatitis B surface antigen should also receive hepatitis B immune globulin as soon after birth as possible and preferably within the first 72 h. Screening for hepatitis C is recommended for individuals at high risk for exposure.

INFECTIONS

BACTERIAL INFECTIONS

Other than bacterial vaginosis, the most common bacterial infections during pregnancy involve the urinary tract (Chap. 130). Many pregnant women have asymptomatic bacteriuria, most likely due to stasis caused by progestational effects on ureteral and bladder smooth muscle and later in pregnancy due to compression effects of the enlarging uterus. In itself, this condition is not associated with an adverse outcome of pregnancy. If asymptomatic bacteriuria is left untreated, symptomatic pyelonephritis may occur. Indeed, ~75% of pregnancy-associated pyelonephritis cases are the result of untreated asymptomatic bacteriuria. All pregnant women should be screened with a urine culture for asymptomatic bacteriuria at the first prenatal visit. Subsequent screening with nitrite/leukocyte esterase strips is indicated for high-risk women, such as those with sickle cell trait or a history of urinary tract infections. All women with positive screens should be treated. Pregnant women who develop pyelonephritis need inpatient IV antibiotic administration due to the elevated risk of urosepsis and acute respiratory distress syndrome in pregnancy. Pregnant women with recurrent urinary tract infections, or one episode of pyelonephritis, should be considered for daily antibiotic suppressive treatment throughout the remainder of their pregnancy.

All pregnant patients are screened prenatally for syphilis, gonorrhea, and chlamydial infections, and the detection of any of these should result in prompt evaluation and treatment (Chaps. 151 and 184).

VIRAL INFECTIONS

Zika Virus (ZV) ZV can be transmitted from mother to fetus throughout gestation and often results in fetal death, severe microcephaly, or other malformations of the central nervous system. Pregnant symptomatic women with relevant epidemiologic exposure within 2 weeks of symptom onset should have serum and urine tested for ZV ribonucleic acid by real-time reverse transcriptase-polymerase chain reaction (RT-PCR). Testing 2–12 weeks after symptom onset utilizes serum measurement of Zika and dengue virus IgM. Sequential obstetrical ultrasound is recommended to assess for fetal growth and anomalies. Couples considering pregnancy should avoid travel to areas with known mosquito transmission of ZV.

Influenza (See also Chap. 195) Pregnant women with influenza are at increased risk of serious complications and death. All women who are pregnant or plan to become pregnant in the near future should receive inactivated influenza vaccine. The prompt initiation of antiviral treatment is recommended for pregnant women in whom influenza is suspected. Treatment can be reconsidered once the results of high-sensitivity tests are available. Prompt initiation of treatment lowers the risk of admission to an intensive care unit and death.

Cytomegalovirus Infection The most common cause of congenital viral infection in the United States is cytomegalovirus (CMV) (Chap. 190). As many as 50–90% of women of childbearing age have antibodies to CMV, but only rarely does CMV reactivation result in neonatal infection. More commonly, primary CMV infection during pregnancy creates a risk of congenital CMV. No currently accepted treatment of CMV infection during pregnancy has been demonstrated to protect the fetus effectively. Moreover, it is difficult to predict which fetus will sustain a life-threatening CMV infection. Severe CMV disease in the newborn is characterized most often by petechiae, hepatosplenomegaly, and jaundice. Chorioretinitis, microcephaly, intracranial calcifications, hepatitis, hemolytic anemia, and purpura may also develop. CNS involvement, resulting in the development of psychomotor, ocular, auditory, and dental abnormalities over time, has been described. Women with a primary CMV infection should delay conception for 6 months.

Rubella (See also Chap. 201) Rubella virus is a known teratogen; first-trimester rubella carries a high risk of fetal anomalies, though the risk significantly decreases later in pregnancy. Congenital rubella may be diagnosed by percutaneous umbilical-blood sampling with the detection of IgM antibodies in fetal blood. All pregnant women and all women of childbearing age should be tested for their immune status to rubella. All women who might become pregnant and who are not immune to rubella should be vaccinated at least 3 months before conception.

Herpesvirus Infection (See also Chap. 187) The acquisition of genital herpes during pregnancy is associated with spontaneous abortion, prematurity, and congenital and neonatal herpes. A cohort study of pregnant women without evidence of previous herpesvirus infection demonstrated that ~2% acquired a new herpesvirus infection during the pregnancy. Approximately 60% of the newly infected women had no clinical symptoms. Infection occurred with equal frequency in all three trimesters. If herpesvirus seroconversion occurred early in pregnancy, the risk of transmission to the newborn was very low. In women who acquired genital herpes shortly before delivery, the risk of transmission was high. The risk of active genital herpes lesions at term can be reduced by prescribing acyclovir for the last 4 weeks of pregnancy to all women who had an episode of genital herpes during the pregnancy.

Herpesvirus infection in the newborn can be devastating. Disseminated neonatal herpes carries with it high mortality and morbidity rates from CNS involvement. It is recommended that pregnant women with active genital herpes lesions at the time of presentation in labor be delivered by cesarean section.

Parvovirus Infection (See also Chap. 192) Parvovirus infection (caused by human parvovirus B19) may occur during pregnancy. It rarely causes sequelae, but susceptible women infected during pregnancy may be at risk for fetal hydrops secondary to erythroid aplasia and profound anemia.

HIV Infection (See also Chap. 197) The predominant cause of HIV infection in children is transmission of the virus from mother to newborn during the perinatal period. All pregnant women should be screened for HIV infection. Factors that increase the risk of mother-to-newborn transmission include high maternal viral load, low maternal CD4+ T cell count, prolonged labor, prolonged duration of membrane rupture, and the presence of other genital tract infections, such as syphilis or herpes. Prior to the widespread use of antiretroviral treatment, the perinatal transmission rate was in the range of 20%. In women with a good response to antiretroviral treatment, the transmission rate is about 1%. Measurement of maternal plasma HIV RNA copy number guides the decision for vaginal versus cesarean delivery. For women with

<1000 copies of plasma HIV RNA/mL who are receiving combination antiretroviral therapy, the risk of transmission to the newborn is ~1% regardless of mode of delivery or duration of membrane rupture. These women may elect to attempt a vaginal birth following the spontaneous onset of labor. For women with a viral load of ≥1000 copies/mL prior to 38 weeks of gestation, a scheduled prelabor cesarean at 38 weeks is recommended to reduce the risk of HIV transmission to the newborn.

VACCINATIONS

(See also Chap. 118) For rubella-nonimmune individuals contemplating pregnancy, measles-mumps-rubella vaccine should be administered, ideally at least 3 months prior to conception, but otherwise in the immediate postpartum period. In addition, pregnancy is not a contraindication for vaccination against influenza, tetanus, diphtheria, and pertussis (Tdap), and these vaccines are recommended for appropriate individuals.

MATERNAL MORTALITY

Maternal death is defined as death occurring during pregnancy or within 42 days of completion of pregnancy from a cause related to or aggravated by pregnancy, but not due to accident or incidental causes. The maternal mortality ratio is the number of maternal deaths per 100,000 live births. From 1935 to 2007, the U.S. maternal mortality ratio decreased from nearly 600/100,000 births to 12.7/100,000 births. Since 2007, the U.S. maternal mortality ratio has increased to 21.5/100,000 births. There are significant health disparities in the maternal mortality ratio. In the United States, in the period from 2005 to 2014, the maternal mortality ratios (per 100,000 live births) by race were 11.3 among Hispanic women, 14.1 among non-Hispanic white women, and 40.2 among non-Hispanic black women. The most common causes of maternal death in the United States today are pulmonary embolism, obstetric hemorrhage, hypertension, sepsis, cardiovascular conditions (including peripartum cardiomyopathy and stroke), and ectopic pregnancy. Specialists in internal medicine play an important role in national efforts to reduce the maternal mortality ratio.

As stated above, the maternal mortality ratio in the United States is about 21.5/100,000 live births. In some countries in sub-Saharan Africa and southern Asia, the maternal mortality ratio is >500/100,000 live births. The most common causes of maternal death in these countries are maternal hemorrhage, hypertensive disorders, infection, obstructed labor, and complications from unsafe pregnancy termination. The health interventions that would have the greatest impact on maternal health include improving the following components of the health system: (1) access to contraceptive services in order to space births and limit total family size; (2) access to safe pregnancy termination; (3) presence of trained birth attendants at all deliveries; and (4) transportation to emergency obstetrical centers that can provide intensive medical and surgical services, including cesarean delivery. Maternal death is a global public-health tragedy that could be mitigated with the application of modest resources.

SUMMARY

With improved diagnostic and therapeutic modalities as well as advances in the treatment of infertility, more patients with serious medical complications will be seeking to become pregnant and will require complex obstetric care. Improved outcomes of pregnancy in these women will be best attained by a team of internists, maternal-fetal medicine (high-risk obstetrics) specialists, pediatricians and anesthesiologists assembled to counsel these patients about the risks of pregnancy and to plan their treatment prior to, and following, conception. The importance of preconception counseling cannot be overstated. It is the responsibility of all physicians caring for women in the reproductive age group to assess their patients' reproductive plans as part of their overall health evaluation.

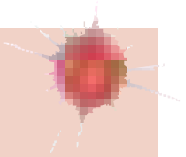
467 Medical Evaluation of the Surgical Patient



Prashant Vaishnava, Kim A. Eagle

Cardiovascular and pulmonary complications continue to account for major morbidity and mortality in patients undergoing noncardiac surgery. Emerging evidence-based practices dictate that the internist should perform an individualized evaluation of the surgical patient to provide an accurate preoperative risk assessment and stratification that will guide optimal perioperative risk-reduction strategies. This chapter reviews cardiovascular and pulmonary preoperative risk assessment, emphasizing the goal-directed management of patients at elevated risk for adverse cardiovascular outcomes in the perioperative period. In addition, perioperative management of diabetes mellitus and prophylaxis of endocarditis and for venous thromboembolism are reviewed.

EVALUATION OF INTERMEDIATE- AND HIGH-RISK PATIENTS

Simple, standardized preoperative screening questionnaires, such as the one shown in Table 467-1, have been developed for the purpose of identifying patients at intermediate or high risk who may benefit from a more detailed clinical evaluation. Evaluation of such patients for surgery should always begin with a thorough history and physical examination and with a 12-lead resting electrocardiogram, in accordance with the American College of Cardiology/American Heart Association guidelines. The history should focus on symptoms of occult cardiac or pulmonary disease. The urgency of the surgery should be determined, as true emergency procedures are associated with unavoidably higher morbidity and mortality risk. Preoperative laboratory testing should be carried out only for specific clinical conditions, as noted during clinical examination. Thus, healthy patients of any age who are undergoing elective surgical procedures without coexisting medical conditions should not require any testing unless the degree of surgical stress may result in unusual changes from the baseline state.

PREOPERATIVE CARDIAC RISK ASSESSMENT

A stepwise approach to cardiac risk assessment and stratification in patients undergoing noncardiac surgery is illustrated in Fig. 467-1. The evaluation begins with characterization of the combined surgical and clinical risk into categories of low (<1%) and elevated risk for major adverse cardiovascular events (MACE). Select surgeries are associated with very low risk for MACE; these surgeries and procedures include select ophthalmologic surgeries (e.g., cataract surgery), select endoscopic procedures, and select superficial procedures. Patients undergoing these low-risk procedures should proceed to surgery without

TABLE 467-1 Standardized Preoperative Questionnaire[a]

1. Age, weight, height
2. Are you:
   Female and 55 years of age or older or male and 45 years of age of older?
   If yes, are you 70 years of age or older?
3. Do you take anticoagulant medications ("blood thinners")?
4. Do you have or have you had any of the following heart-related conditions?
   Heart disease
   Heart attack within the last 6 months
   Angina (chest pain)
   Irregular heartbeat
   Heart failure
5. Do you have or have you ever had any of the following?
   Rheumatoid arthritis
   Kidney disease
   Liver disease
   Diabetes
6. Do you get short of breath when you lie flat?
7. Are you currently on oxygen treatment?
8. Do you have a chronic cough that produces any discharge or fluid?
9. Do you have lung problems or diseases?
10. Have you or any blood member of your family ever had a problem other than nausea with any anesthesia?
    If yes, describe:
11. If female, is it possible that you are pregnant?
    Pregnancy test:
    Please list date of last menstrual period:

[a]University of Michigan Health System patient information report. Patients who answer yes to any of questions 2–9 should receive a more detailed clinical evaluation.

further testing. Clinical risk may be estimated with the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) risk calculator (*http://www.riskcalculator.facs.org*) or with calculation of the Revised Cardiac Risk Index (RCRI).

Previous studies have compared several cardiac risk indices. The American College of Surgeons' National Surgical Quality Improvement Program prospective database has identified five predictors of perioperative myocardial infarction (MI) and cardiac arrest based on increasing age, American Society of Anesthesiologists class, type of surgery, dependent functional status, and abnormal serum creatinine level. However, given its accuracy and simplicity, the RCRI **(Table 467-2)** is often the favored risk index. The RCRI relies on the presence or absence of six identifiable predictive factors: high-risk surgery, ischemic heart disease, congestive heart failure, cerebrovascular disease, diabetes mellitus treated with insulin, and renal insufficiency with a creatinine >2.0 mg/dL. Each of these predictors is assigned one point. The risk of major cardiac events—defined as MI, pulmonary edema, ventricular fibrillation or primary cardiac arrest, and complete heart block—can then be predicted. Based on the presence of none, one, two, three, or more of these clinical predictors, the rate of development of one of these four major cardiac events is estimated to be 0.4, 0.9, 7, and 11%, respectively **(Fig. 467-2)**. An RCRI score of 0 signifies a 0.4–0.5% risk of cardiac events; RCRI 1, 0.9–1.3%; RCRI 2, 4–7%; and RCRI ≥3, 9–11%. The clinical utility of the RCRI is to identify patients with three or more predictors who are at very high risk (≥11%) for cardiac complications and who may benefit from further risk stratification with noninvasive cardiac testing, initiation of preoperative preventive medical management, or avoidance of surgery.

For patients at elevated combined clinical and surgical risk for MACE, the stepwise perioperative cardiac assessment for coronary artery disease (CAD) proceeds with consideration of functional capacity. Participation in activities of daily living offers an expression of functional capacity, often expressed in terms of metabolic equivalents (METs). For predicting perioperative events, poor exercise tolerance has been defined as the inability to walk four blocks or climb two flights of stairs at a normal pace or to meet a MET level of 4 (e.g., carrying objects of 15–20 lb or playing golf or doubles tennis) because of the development of dyspnea, angina, or excessive fatigue **(Table 467-3)**. Patients with moderate or greater (≥4 METs) functional capacity (e.g., climbing up a flight of stairs, walking up a hill, or walking on level ground at 4 mph) generally should not undergo further non-invasive cardiac testing prior to elective non-cardiac surgery. Those patients with poor (<4 METs) or unknown functional capacity should undergo pharmacological stress testing if the results of such testing would impact decision-making or perioperative care.

PREOPERATIVE NONINVASIVE CARDIAC TESTING FOR RISK STRATIFICATION

There is little evidence to support widespread application of preoperative noninvasive cardiac testing for all patients undergoing major surgery. The current paradigm to guide the need for noninvasive cardiac testing is to perform such testing in patients with poor or unknown capacity if it would alter clinical management or modify perioperative care. Options for pharmacological stress testing include dobutamine stress echocardiography or myocardial perfusion imaging with coronary vasodilator stress (dipyridamole, adenosine, or regadenoson) with thallium-201 and/or technetium-99m. Routine screening with noninvasive stress testing is not recommended in patients at low risk for noncardiac surgery. Furthermore, coronary revascularization before noncardiac surgery is not recommended for the express purpose of reducing perioperative cardiac events. That said, revascularization before noncardiac surgery should be considered in patients if it would be indicated regardless of the surgery planned and instead according to clinical practice guidelines. In the Coronary Artery Revascular Prophylaxis trial, there were no differences in perioperative and long-term cardiac outcomes with or without preoperative coronary revascularization; of note, patients with left main disease were excluded.

RISK MODIFICATION: PREVENTIVE STRATEGIES TO REDUCE CARDIAC RISK

Perioperative Coronary Revascularization *Prophylactic* coronary revascularization with either coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI) provides no short- or mid-term survival benefit for patients *without* left main CAD or three-vessel CAD in the presence of poor left ventricular systolic function and is *not recommended* for patients with stable CAD before noncardiac surgery. Although PCI is associated with lower procedural risk than is CABG in the perioperative setting, the placement of a coronary artery stent soon before noncardiac surgery may increase the risk of bleeding during surgery if dual antiplatelet therapy (DAPT) (aspirin and thienopyridine) is administered; moreover, stent placement shortly before noncardiac surgery increases the perioperative risk of MI and cardiac death due to stent thrombosis if such therapy is withdrawn prematurely **(Chap. 270)**. It is recommended that, if possible, elective noncardiac surgery be delayed 30 days after placement of a bare metal intracoronary stent and ideally for 6 months after deployment of a drug-eluting stent. Contemporary stent platforms allow for greater flexibility in the earlier interruption of DAPT; current clinical practice guidelines do suggest consideration of elective noncardiac surgery 6 months after drug eluting stent (DES) implantation if the risk of further delaying surgery exceeds the risk of stent thrombosis/myocardial ischemia. For patients who *must* undergo noncardiac surgery early (>14 days) after PCI, balloon angioplasty without stent placement appears to be a reasonable alternative because DAPT is not necessary in such patients.

PERIOPERATIVE PREVENTIVE MEDICAL THERAPIES The goal of perioperative preventive medical therapies with β-adrenergic antagonists, hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins), and antiplatelet agents is to reduce perioperative adrenergic stimulation, ischemia, and inflammation, all of which are heightened during the perioperative period.

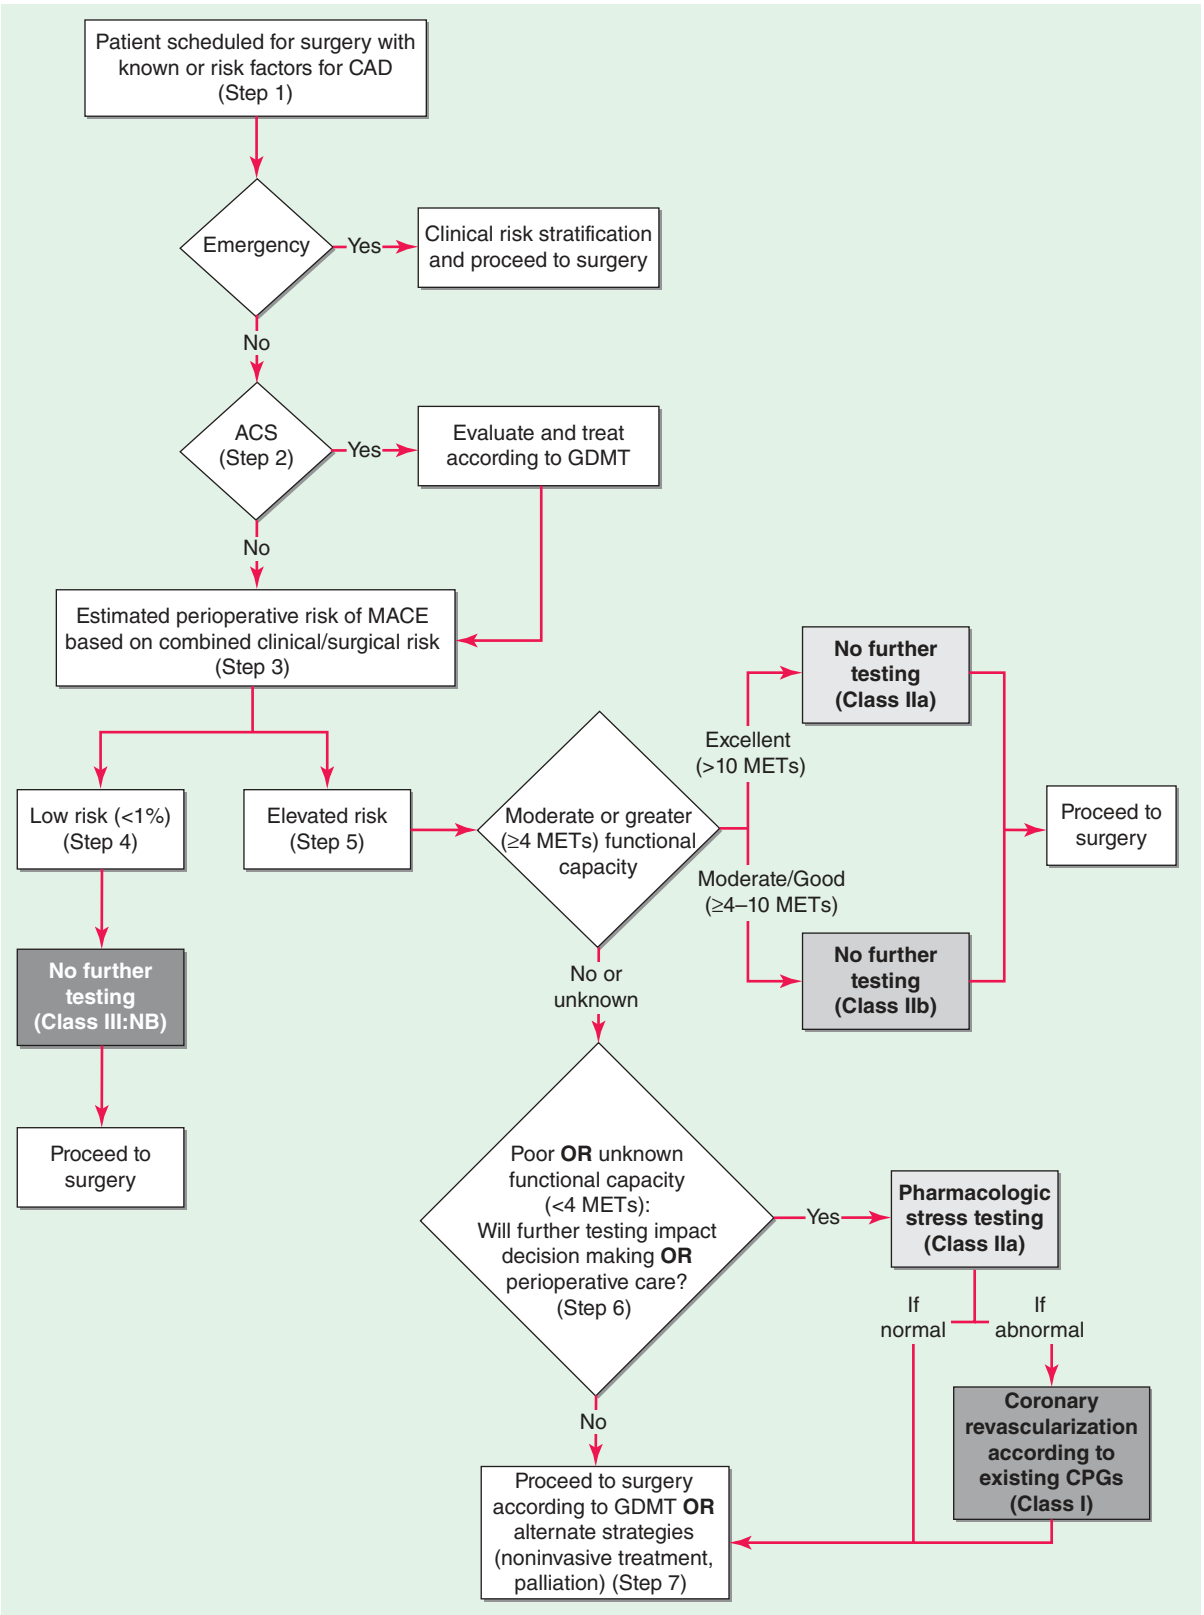

FIGURE 467-1 Composite algorithm for cardiac risk assessment and stratification in patients undergoing noncardiac surgery. Preoperative evaluation involves a stepwise clinical evaluation. Those individuals requiring emergency surgery should proceed without further risk stratification. Acute coronary syndrome (step 2) should be evaluated and treated, accordingly to goal-directed medical therapy. For patients awaiting non-emergent surgeries and without acute coronary syndrome, perioperative risk is a combination of clinical and surgical risk. Select procedures and surgeries (e.g., select endoscopic procedures) are associated with low perioperative (<1%) risk and no further clinical testing is generally necessary. For those procedures associated with elevated risk, an assessment of functional capacity informs the decision for further testing. Those individuals with moderate or greater functional capacity do not require further testing and should proceed to surgery. Individuals with poor or unknown functional capacity may require pharmacologic stress testing if it would change decision-making or perioperative care. *(From LA Fleisher et al: Circulation 2014;130:e278-e333, with permission.)*

TABLE 467-2 Clinical Markers Included in the Revised Cardiac Risk Index

High-Risk Surgical Procedures
Vascular surgery (except carotid endarterectomy)
Major intraperitoneal or intrathoracic procedures
Ischemic Heart Disease
History of myocardial infarction
Current angina considered to be ischemic
Requirement for sublingual nitroglycerin
Positive exercise test
Pathological Q-waves on ECG
History of PCI and/or CABG with current angina considered to be ischemic
Congestive Heart Failure
Left ventricular failure by physical examination
History of paroxysmal nocturnal dyspnea
History of pulmonary edema
S_3 gallop on cardiac auscultation
Bilateral rales on pulmonary auscultation
Pulmonary edema on chest x-ray
Cerebrovascular Disease
History of transient ischemic attack
History of cerebrovascular accident
Diabetes Mellitus
Treatment with insulin
Chronic Renal Insufficiency
Serum creatinine >2 mg/dL

Abbreviations: CABG, coronary artery bypass grafting; ECG, electrocardiogram; PCI, percutaneous coronary interventions.

B-ADRENERGIC ANTAGONISTS The use of perioperative beta blockade should be based on a thorough assessment of a patient's perioperative clinical and surgery-specific cardiac risk (e.g., as with the RCRI). The paradigm for beta blockade in the perioperative period has shifted in recent years owing, firstly, to the publication of the PeriOperative Ischemic Evaluation (POISE) trial demonstrating that, while perioperative beta blockade reduces the perioperative risk for MI, this is at the expense of increased death and stroke. Regarding POISE, this trial has been criticized for the use of an excessive dose of beta blocker in the perioperative period and one that may not be reflective of clinical practice, nor one that was titrated in the days or weeks preceding the procedure or surgery. Secondly, research misconduct has discredited the Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography (DECREASE) family of studies, which previously contributed to the bedrock of data supporting the use of perioperative beta blockade but have now been retracted.

Current guidelines emphasize the following key points:

1. Continuation of beta blockade in patients undergoing surgery and who have been receiving such therapy chronically.
2. Avoidance of beta-blocker withdrawal or initiation on the day of surgery.
3. Consideration of initiation of beta-blocker therapy perioperatively (ideally far enough in advance to assess safety and tolerability) in very select high-risk patients, namely, those with intermediate- or high-risk ischemia or three more RCRI risk factors.

HMG-COA REDUCTASE INHIBITORS (STATINS) A number of prospective and retrospective studies support the perioperative prophylactic use of statins for reduction of cardiac complications in patients with established atherosclerosis. For patients undergoing noncardiac surgery and currently taking statins, statin therapy *should be continued* to reduce perioperative cardiac risk. Initiation of statin therapy is *reasonable* for patients undergoing vascular surgery independent of clinical risk. Perioperative initiation of statin therapy should be considered in patients undergoing elevated risk procedures if there is an indication for such therapy separate from the surgery and according to clinical practice guidelines.

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS It is important to maintain continuity of therapy with ACE inhibitors (when such therapy is used for the treatment of heart failure or hypertension).

ORAL ANTIPLATELET AGENTS The 4- to 6-week period following implantation of an intracoronary stent (bare metal or drug eluting) constitutes the period of time of greatest risk for the development of stent thrombosis. If possible, noncardiac surgery should be avoided in this vulnerable period. The duration of DAPT thereafter is dictated by the circumstances in which PCI was performed and whether the indication was stable ischemic heart disease or acute coronary syndrome. For the former among patients treated with a drug eluting stent, dual anti-platelet therapy should be given for at least 6 months. For the latter, dual anti-platelet therapy should be given for at least 12 months. However, DAPT may be interrupted to allow for noncardiac surgery 30 days after BMS and 6 months after DES, respectively. If $P2Y_{12}$ inhibitor therapy (clopidogrel, prasugrel, or ticagrelor) is interrupted or discontinued in patients who have received intracoronary stents, aspirin should be continued perioperatively (save select circumstances where the risk of bleeding may be catastrophic as in neurosurgical or spinal procedures) and the $P2Y_{12}$ receptor inhibitor should be restarted as soon as possible post-operatively. Decisions surrounding antiplatelet management in the perioperative setting among patients who have received intracoronary stents are complex and should involve multidisciplinary decision-making.

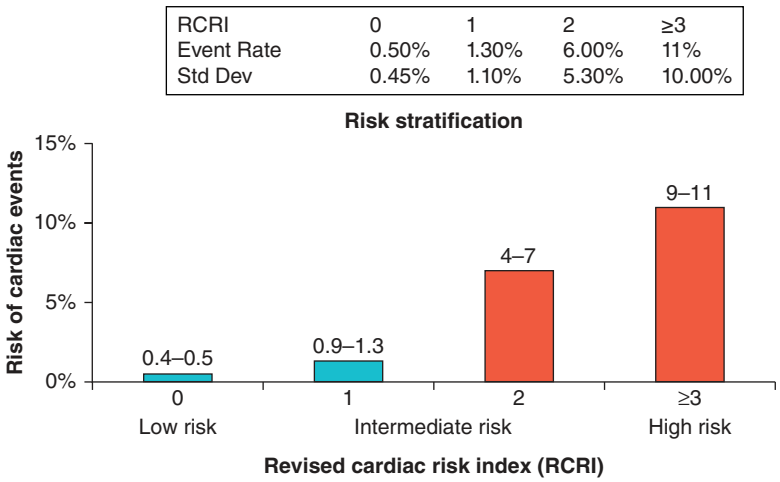

FIGURE 467-2 Risk stratification based on the revised cardiac risk index; derivation and prospective validation of a simple index for prediction of cardiac risk in patients undergoing major noncardiac surgery. Cardiac events include myocardial infarction, pulmonary edema, ventricular fibrillation, cardiac asystole, and complete heart block. *(Adapted from TH Lee et al: Circulation 100:1043, 1999.)*

α_2 AGONISTS Based on the results of POISE-2 (a large multicenter, international, blinded randomized clinical trial of aspirin and clonidine), α_2 agonists for prevention of cardiac events are not recommended in patients who are undergoing noncardiac surgery. In this trial, clonidine increased the rate

TABLE 467-4 Gradation of Mortality Risk of Common Noncardiac Surgical Procedures

Higher	• Emergent major operations, especially in the elderly • Aortic and other noncarotid major vascular surgery (endovascular and nonendovascular) • Prolonged surgery associated with large fluid shift and/or blood loss
Intermediate	• Major thoracic surgery • Major abdominal surgery • Carotid endarterectomy surgery • Head/neck surgery • Orthopedic surgery • Prostate surgery
Lower	• Eye, skin, and superficial surgery • Endoscopic procedures

Source: From LA Fleisher et al: Circulation 116:1971, 2007, with permission.

of nonfatal cardiac arrest and clinically important hypotension, while reducing the rate of death or nonfatal MI.

CALCIUM CHANNEL BLOCKERS Evidence is lacking to support the use of calcium channel blockers as a prophylactic strategy to decrease perioperative risk in major noncardiac surgery.

ANESTHETICS Mortality risk is low with safe delivery of modern anesthesia, especially among low-risk patients undergoing low-risk surgery (Table 467-4). Inhaled anesthetics have predictable circulatory and respiratory effects: all decrease arterial pressure in a dose-dependent manner by reducing sympathetic tone and causing systemic vasodilation, myocardial depression, and decreased cardiac output. Inhaled anesthetics also cause respiratory depression, with diminished responses to both hypercapnia and hypoxemia, in a dose-dependent manner; in addition, these agents have a variable effect on heart rate. Prolonged residual neuromuscular blockade also increases the risk of postoperative pulmonary complications due to reduction in functional residual lung capacity, loss of diaphragmatic and intercostal muscle function, atelectasis, and arterial hypoxemia from ventilation-perfusion mismatch.

Several meta-analyses have shown that rates of pneumonia and respiratory failure are lower among patients receiving neuroaxial anesthesia (epidural or spinal) rather than general anesthesia. However, there were no significant differences in cardiac events between the two approaches. Evidence from a meta-analysis of randomized controlled trials supports postoperative epidural analgesia for >24 h for the purpose of pain relief. However, the risk of epidural hematoma in the setting of systemic anticoagulation for venous thromboembolism prophylaxis (see below) and postoperative epidural catheterization must be considered.

PREOPERATIVE PULMONARY RISK ASSESSMENT

Perioperative pulmonary complications occur frequently and lead to significant morbidity and mortality. Clinical practice guidelines recommend the following:

1. All patients undergoing noncardiac surgery should be assessed for risk of pulmonary complications (Table 467-5).
2. Patients undergoing emergency or prolonged (3–4 h) surgery; aortic aneurysm repair; vascular surgery; major abdominal, thoracic, neurologic, head, or neck surgery; and general anesthesia should be considered to be at elevated risk for postoperative pulmonary complications.
3. Patients at higher risk of pulmonary complications should undergo incentive spirometry, deep-breathing exercises, cough encouragement, postural drainage, percussion and vibration, suctioning and ambulation, intermittent positive-pressure breathing, continuous positive airway pressure, and selective use of a nasogastric tube for postoperative nausea, vomiting, or symptomatic abdominal distention to reduce postoperative risk. Multiple pulmonary risk indices are available to estimate the postoperative risk of respiratory failure, pneumonia, and other pulmonary complications; among these is the ARISCAT risk index, which accounts for the following seven risk factors: age, low preoperative oxygen saturation, respiratory infection within the preceding month, upper abdominal or thoracic surgery, surgery lasting >2 h, and emergency surgery (Table 467-6).
4. Preoperative spirometry and chest radiography should not be used routinely for predicting risk of postoperative pulmonary complications but may be appropriate for patients with chronic obstructive pulmonary disease or asthma.
5. Spirometry is of value before lung resection in determining candidacy for coronary artery bypass; however, it does not provide a spirometric threshold for extrathoracic surgery below which the risks of surgery are unacceptable.

TABLE 467-5 Predisposing Risk Factors for Pulmonary Complications

1. Upper respiratory tract infection: cough, dyspnea
2. Age >60 years
3. Chronic obstructive pulmonary disease
4. Cigarette use
5. American Society of Anesthesiologists Class ≥2
6. Functional dependence
7. Congestive heart failure
8. Serum albumin <3.5 g/dL
9. Obstructive sleep apnea
10. Impaired sensorium (confusion, delirium, or mental status changes)
11. Abnormal findings on chest examination
12. Alcohol use
13. Weight loss
14. Spirometry threshold before lung resection
    a. FEV_1 <2 L
    b. MVV <50% of predicted
    c. PEF <100 L or 50% predicted value
    d. PCO_2 ≥45 mmHg
    e. PO_2 ≤50 mmHg

Abbreviations: FEV_1, forced expiratory volume in 1 s; MVV, maximal voluntary ventilation; PEF, peak expiratory flow rate; PCO_2, partial pressure of carbon dioxide; PO_2, partial pressure of oxygen.

TABLE 467-6 Risk Modification to Reduce Perioperative Pulmonary Complications

Preoperatively
• Cessation of smoking for at least 8 weeks before and until at least 10 days after surgery
• Training in proper lung expansion techniques
• Inhalation bronchodilator and/or steroid therapy, when indicated
• Control of infection and secretion, when indicated
• Weight reduction, when appropriate
Intraoperatively
• Limited duration of anesthesia
• Avoidance of long-acting neuromuscular blocking drugs, when indicated
• Prevention of aspiration and maintenance of optimal bronchodilation
Postoperatively
• Optimization of inspiratory capacity maneuvers, with attention to:
◦ Mobilization of secretions
◦ Early ambulation
◦ Encouragement of coughing
◦ Selective use of a nasogastric tube
◦ Adequate pain control without excessive narcotics

Source: From VA Lawrence et al: Ann Intern Med 144:596, 2006, and WF Dunn, PD Scanlon: Mayo Clin Proc 68:371, 1993.

6. Pulmonary artery catheterization, administration of total parenteral nutrition (as opposed to no supplementation), or total enteral nutrition have no consistent benefit in reducing postoperative pulmonary complications.

PERIOPERATIVE MANAGEMENT AND PROPHYLAXIS

DIABETES MELLITUS

(See also Chaps. 396–398) Many patients with diabetes mellitus have significant symptomatic or asymptomatic CAD and may have silent myocardial ischemia due to autonomic dysfunction. Intensive (versus lenient) glycemic control in the perioperative period is generally not associated with improved outcomes, and may increase the risk of hypoglycemia. Practice guidelines advocate a target glucose range from 100 to 180 mg/dL in the perioperative period. Oral hypoglycemic agonists should not be given on the morning of surgery. Perioperative hyperglycemia should be treated with IV infusion of short-acting insulin or SC sliding-scale insulin. Patients whose diabetes is diet controlled may proceed to surgery with close postoperative monitoring.

INFECTIVE ENDOCARDITIS

(See also Chap. 123) Prophylactic antibiotics should be administered to the following patients before dental procedures that involve manipulation of gingival tissue, manipulation of the periapical region of teeth, or perforation of the oral mucosa: those with prosthetic cardiac valves (including transcatheter prosthetic valves); prosthetic material used in valve repair (annuloplasty ring or artificial chord); previous infective endocarditis; cardiac transplant recipients with valvular regurgitation from a structurally abnormal valve; and unrepaired cyanotic congenital heart disease or repaired congenital heart disease, with residual shunts or valvular regurgitation at the site of adjacent to the site of a prosthetic patch or prosthetic device.

VENOUS THROMBOEMBOLISM

(See also Chap. 273) Perioperative prophylaxis of venous thromboembolism should follow established guidelines of the American College of Chest Physicians. Aspirin is not supported as a single agent for thromboprophylaxis. Low-dose unfractionated heparin (≤5000 units SC bid), low-molecular weight heparin (e.g., enoxaparin, 30 mg bid or 40 mg qd), or a pentasaccharide (fondaparinux, 2.5 mg qd) is appropriate for patients at moderate risk; unfractionated heparin (5000 units SC tid) is appropriate for patients at high risk. Graduated compression stockings and pneumatic compression devices are useful supplements to anticoagulant therapy or in patients at excessive bleeding risk.

468 Behavioral Economics and Health

Kevin G. Volpp, George Loewenstein, David A. Asch

Tobacco use, physical inactivity, unhealthy diet, excessive alcohol use, and other individual behaviors are estimated to underlie 40% of premature mortality in the United States. Approximately 75% of the $3 trillion currently spent on health care in the United States is attributable to cancer, heart disease, type 2 diabetes, and obesity, and each of these conditions is strongly influenced by behavior. Nearly one-half of patients prescribed medications to lower their cholesterol within 1 year following myocardial infarction stop taking these drugs—even when they are provided free of charge. Despite great advances in the science and technology of health care, a large gap separates theoretically achievable goals in health and health care from what individuals and populations actually reach. Human behavior is both a major contributor to health problems and a barrier to the successful implementation of solutions to address them.

Recognizing that there are many reasons people do not take action to improve their health, behavior change experts have focused efforts on strategies targeted at individual behavior, introducing incentives for weight loss and smoking cessation, environmental strategies such as mandated food labeling, and combination approaches. For example, Section 2705 of the Affordable Care Act (ACA) allows employers to provide incentives of up to 50% of total premiums based on outcomes such as reduced body mass index, lowered blood pressure or cholesterol, and smoking cessation; this legislation puts as much as $300 billion worth of employee health incentives in play annually.

Many of these approaches have built-in limitations, largely because they have been designed around the pervasive view that people always act to improve their self-interest. Existing policy solutions presuppose that health care decisions are rationally based economic transactions and that rational people will dispassionately assess the net present value of the costs and benefits of alternative paths and pursue the best path forward. These approaches are normatively appealing but seem better suited to support the health of people who behave as economists assume they do, and perhaps less effective when exposed to such realities of human behavior as limited attention, overconfidence, and problems of self-control. It is not just the magnitude of incentives that matters, but also other critical features such as the specific nature of rewards, feedback frequency, saliency, and framing. Public health programs, including those involving financial incentives, are more likely to achieve their goals if designed based not on how perfectly rational people *ought* to make health decisions but rather on how humans *actually* make them. The field of behavioral economics, which uses insights from psychology to identify ways that human decision-making often falls short of the ideal, and which offers a more realistic account of human behavior, provides a natural framework for such efforts, including a range of insights relevant to understanding how people respond to financial and nonfinancial (e.g., health) incentives.

CONCEPTS OF CLASSICAL ECONOMICS AND HOW THEY DIFFER FROM BEHAVIORAL ECONOMICS

Classical economics posits that individuals are rational utility maximizers, meaning that they are able to dispassionately identify alternative decisions, calculate the probabilities of and utility/disutility for each potential outcome, and then, through a process of backward induction, implement the decision that has the highest net present value. When it comes to health behaviors, classical economic theory would assume that if people are obese they must have decided that the costs of obesity are outweighed by the benefits of the behaviors that lead to it and that if people smoke they must have decided that the pleasures of doing so outweigh the costs. This assumption of rational utility maximization has two major consequences for public policy, both of which are applicable in the health domain.

The first is that conventional economic thinking radically limits the range of situations in which it makes sense to intervene at a policy level. Under the assumptions of conventional economics, regulatory interventions such as targeted taxes and subsidies are considered appropriate only in situations characterized by externalities (costs that an individual's actions impose on others such as second-hand cigarette smoke), the presence of "market failures" (e.g., monopolies), or the presence of certain types of information asymmetries. The second is that standard economics offers a relatively restricted array of policy tools, including taxes, subsidies, and mandates regarding information provision, and makes unrealistic assumptions about how each of these approaches will influence the behavior of individuals.

Behavioral economics builds on conventional economics by enriching its conception of individual behavior, offering enhancements on both of these dimensions. First, it broadens the range of situations in which policy interventions make sense by introducing the notion of "internalities." While externalities are costs (or benefits) individual behaviors impose on others, internalities are the costs individuals impose on themselves—typically their future selves. While interventions to address smoking and obesity can be justified on externality grounds (e.g., the health care costs are borne by individuals other than the immediately affected individual), they can also be justified on grounds of internalities—e.g., people often irrationally discount the delayed consequences of their behavior. In that sense people might want to be protected not just from others, but from the decisions of their prior selves. Policy intervention can be further justified by the ubiquitous exploitation of individual weaknesses by businesses. Commercial enterprises may take advantage of such vulnerabilities for individual profit rather than customer health, such as with the formulation of tempting but unhealthy processed foods or the pricing of meal "deals" that do not account for the health consequences of economically predatory offers. This behavior is found across industries: Credit card companies and automobile manufacturers lure new customers with "$0 down" and fleeting but appealing teaser rates of "0% interest," playing on the common propensity to focus on the present rather than on the future. Banks earn revenue by charging high fees for minor mistakes such as account overdrafts or breaches of minimum balance rules hiding the description of such fees in small print and complicated jargon. States market lottery tickets that return $0.45 on the dollar and promote these games in ways that ignore more realistic expectations using one-sided messages such as "you can't win if you don't play" rather than, for example, the equally accurate message, "you can't lose if you don't play."

Second, behavioral economics substantially broadens the range of potential policy interventions far beyond those offered by traditional economics. Behavioral economics has become best known for the concepts of "libertarian paternalism" and "asymmetric paternalism." In contrast to "heavy-handed" paternalism, asymmetric paternalism attempts to protect people without limiting freedom of choice. That is, it is asymmetric because it seeks to help individuals who are prone to making irrational decisions without restricting the freedom of choice of others making informed, deliberate decisions. For example, arranging the presentation of food in a cafeteria line so that the healthy foods appear first is likely to increase the amount of healthy food chosen, without depriving those who want the unhealthy foods of the opportunity to purchase them. People who believe that individuals behave optimally should not object to asymmetric paternalism because it does not limit freedom, and those who acknowledge the limits of human rationality should endorse such measures. Frequently, these measures are called "nudges."

A nudge has been defined as "any aspect of the choice architecture that alters people's behavior in a predictable way without forbidding any options or significantly changing their economic incentives. To count as a mere nudge, the intervention must be easy and cheap to avoid." The most prominent, and to date successful, application of nudges has been the use of defaults to increase enrollment in defined contribution retirement savings plans, and secondarily the use of automatic escalation to encourage higher savings rates. These ideas and research findings have had a major impact on retirement savings policies worldwide, including the Pension Protection Act of 2006 in the United States. Building on this success story in savings, and bolstered by the establishment of so-called "nudge units" worldwide, the nudge agenda has positioned behavioral economics at the center of public policy.

The applicability of behavioral economics to policy, including health-related policies, however, goes well beyond nudges. Many health-relevant insights from behavioral economics do not fit the definition of a nudge. For example, there have been incentive programs aimed at changing health behaviors for maximum cost-effectiveness, improvements in the delivery of health-related information, such as nutrition labels, and new designs for physician incentives or health insurance. A common theme of this work harnesses natural tendencies toward predictable decision errors by redirecting those tendencies to help people achieve longer-term health goals or other socially valuable purposes, much the way some martial arts redirect an adversary's strength against him.

Many of the same messages, incentives, and choice structures used so effectively to lure people into self-destructive health behaviors can be redirected to attract them to healthier choices that improve their long-term health and well-being. Some features of human decision-making, such as our propensity to experience regret when we make a bad choice, and our aversion to putting ourselves into such situations (a phenomenon known as "regret aversion" and arguably not really an example of an error) are additionally important features of human psychology that can be exploited in the service of improving health behaviors and outcomes.

There is a common misconception that if you deploy financial incentives in order to promote behavior change, then you are engaged in behavioral economics. But that kind of activity is not behavioral economics; it is simply economics. Indeed, a large number of everyday transactions, such as being paid to go to work, or getting a fine for parking in the wrong place, reflect traditional economic incentives to encourage or discourage certain behaviors. A central lesson from the field of behavioral economics is that how incentives are delivered can matter more than their objective magnitude. There are ways of delivering large incentives that make them ineffective in changing behavior, and there are ways that can greatly magnify the effectiveness of comparatively small incentives. This observation is a source of optimism, implying that with careful design we can leverage relatively small investments to improve public health.

USING BEHAVIORAL ECONOMICS TO PROMOTE SELF-BENEFICIAL HEALTH BEHAVIORS

Behavioral economics builds on neoclassical economics, which has at its core *expected utility theory*. Expected utility theory both presumes to describe how people make decisions and offers a prescription for how such decisions should be made. While utility maximization is a powerful normative model of how we ought to behave, it turns out to be a poor descriptive model of how real people actually behave. Efforts to alter human behavior that rely on this incomplete model often fall short.

Over the past several decades, behavioral economics has described various ways in which people's decisions differ from standard economic models (Table 468-1). While economists mapped out concepts of "bounded rationality" in the 1950s and identified limitations in the dominant expected utility model of decision making under risk, the publication of Prospect Theory by Kahneman and Tversky is widely credited with being seminal in the development of behavioral economics. Prospect theory provides an overarching conceptual framework for describing observations about human behaviors that could not be explained by expected utility theory.

Table 468-1 Traditional vs Behavioral Economics

TRADITIONAL ECONOMICS	BEHAVIORAL ECONOMICS
Core theory: Expected utility maximization	Core theory: Prospect theory
Assumes perfect rationality	Recognizes that people make decision errors
Starting point independent	Assessment depends on your starting point
Framing doesn't matter	Framing affects assessment even when utilities are the same
Stable preferences	Time-inconsistent preferences
People discount the future at constant rates	People discount the near future to a greater degree and have time inconsistent discounting
Intervene only when my actions adversely affect others (negative externalities)	Consider interventions when people will harm their future selves (internalities)
Regulations and policies generally geared to protecting people from the actions of others	Regulations and policies often geared to protecting people from themselves

Although these deviations from expected utility theory can be seen as psychological foibles and errors, the real value of this work has come less from identifying these errors, and more from recognizing that they occur in predictable ways. It is the predictability of these errors that allows the design of strategies to overcome them (Table 468-2). Indeed, it is the predictability and reliability of a number of key features of human decision-making identified by behavioral economics, including but not limited to those connected to prospect theory, allows them to be used in order to promote self-advantageous health-related behaviors.

Loss Aversion and Framing Effects Key tenets of prospect theory include (1) how people feel about a set of possible outcomes depends on their starting point; this is the notion of reference-dependence in which decision-makers evaluate outcomes as gains or losses depending on their starting point; (2) people dislike losses much more than they like equivalent-sized gains, a phenomenon known as "loss aversion"; and (3) there is diminished sensitivity to both gains and losses (Fig. 468-1).

One example of how we can apply the insights of loss aversion can be seen in designing provider payment systems. Financial incentives to physicians to achieve quality goals might be presented—"framed" in the language of behavioral economics—as either rewards (in which physicians receive a bonus if, for example, they increase their colorectal cancer screening rates or increase the percentage of their patients who reach a glycosylated hemoglobin target) or penalties (in which physicians would fail to receive an expected payment if they do not

TABLE 468-2 Key Decision Errors and Suggestions for Addressing Them

Present-biased preferences	Provide feedback and rewards quickly
Nonlinear probability weighting	Motivate people with probabilistic rewards (lotteries)
Overoptimism and loss aversion	Get people to precommit and put money at risk as an effective motivational tool
Peanuts effect	Deliver rewards in bundles, avoiding many small rewards
Narrow bracketing	Frame rewards in terms of effort per day rather than per month or year
Regret aversion	Help people anticipate the regret of poor choices
Defaults/status quo bias	Change the architecture or environment of choice to shift the path of least resistance to favor healthy decisions
Rational world bias	Move beyond the assumption that simply providing information will lead to desired behaviors

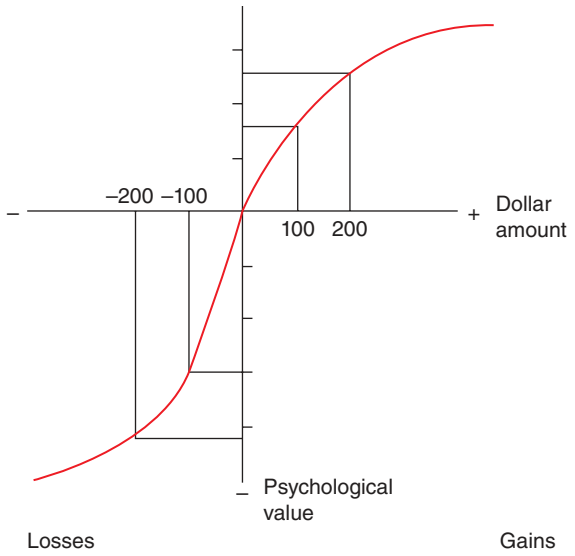

FIGURE 468-1 Prospect theory. (*From D Kahneman: Thinking, Fast and Slow. New York, NY: Farrar, Straus and Giroux, 2011.*)

meet these targets). Classical economists would consider equivalently sized rewards and penalties as identically motivating because each reflects a structure in which one receives $X for a certain outcome (Fig. 468-1). However, loss aversion reminds us that the disutility of losing money is much greater than the utility of gaining the same amount of money. A number of studies have shown that people have a "loss aversion ratio" in a range of 1.5 to 2.5. That means that a potential penalty of $1000 for failing to meet a quality target ought to be about as potent a motivator as a potential reward of $1500 to $2500 for meeting the same target. That multiplier is nonsensical from the standpoint of classical economics, but as an empirically verifiable descriptor of human behavior, it can be exploited in the designs of programs for clinicians or patients to improve health.

In a now classic example in public health, Tversky and Kahneman presented research participants with the following problem:

> *Imagine that the United States is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the program are as follows:*
> *If program A is adopted, 200 people will be saved*
> *If program B is adopted, there is a one-third probability that 600 people will be saved and a two-thirds probability that no one will be saved.*

Given these choices, a substantial majority (about 70%) choose Option A. People preferred to remove uncertainty in favor of the sure bet of saving 200 lives.

A randomly selected second group was presented with an alternative frame:

> *If program A′ is adopted, 400 people will die.*
> *If program B′ is adopted, there is a one-third probability that no one will die and a two-thirds probability that 600 people will die.*

About 70% of participants in this group choose option B′. However, in a population of 600 people, 200 people surviving (option A) is equivalent to 400 people dying (option A′) and options B and B′ are similarly different statements of the same outcome. When outcomes are viewed as gains, as they are in the choice between A and B, decision-makers tend to avoid gambles and are risk averse, choosing option A. When choosing between two bad outcomes, as in the choice between A′ and B′, decision-makers tend to take a gamble (be risk seeking), choosing option B′. In this case people would rather take a chance that everyone could be saved rather than consign themselves to a choice that involved a large number of deaths with 100% certainty.

All of us—including physicians—are highly susceptible to how information is framed. In a set of experiments patients, students, and physicians were presented cases of lung cancer that could be treated either by surgery or radiation therapy. Among all three groups, the choice of surgery was more popular when its outcomes were framed in terms of the probability of survival (e.g., a 68% chance of living for more than 1 year) rather than in terms of the probability of death (e.g., a 32% chance of dying by the end of 1 year). We can say that such sensitivity to framing is irrational since a 68% chance of survival is logically equivalent to a 32% chance of dying—but these irrational decisions fall into predictable patterns of behavior, and that predictability can be used to influence those decisions. This means that clinicians have enormous opportunities to lead patients toward particular decisions by framing the outcomes of those decisions in specific ways, even as they remain truthful. Such an understanding could lead to the view that clinicians should be careful to balance their framing (for example, by following up the statement of 68% chance of survival with a statement like "That means there is a 32% chance of death") in order to provide information in a way that is likely to lead to a particular choice. Alternatively, it could lead to the view that clinicians should deliberately frame outcomes in certain ways in order to lead patients to particular choices—a much more paternalistic stance. Patients often rely on trusted clinicians to help them make the best decisions and, in some settings, that reliance may justify using the principles of behavioral economics strategically even if the same actions in other settings might be seen as paternalistic, anti-libertarian, or coercive.

Loss Aversion and Overoptimism The power of loss aversion can be most effectively leveraged when combined with a well-documented decision error: overoptimism, or unrealistically high expectations about future outcomes. Overoptimism is especially pronounced in the context of people's predictions about their own likelihood of exerting self-control, sometimes referred to as the "false hope syndrome." Although in some contexts overoptimism seems to be beneficial, it can also result in suboptimal patterns of behavior. For example, people prefer paying a flat rate for gym memberships even though they would spend less if they were to pay on a per-visit basis, in part because they overestimate their future gym attendance.

As described earlier, loss aversion reflects the tendency to put greater weight on losses than on equivalently sized gains. It can produce a variety of undesired behaviors, from excessive risk aversion to the tendency for people to hold on to losing investments, such as houses or stocks for too long.

Loss aversion can, in theory, be deployed to advance social goals by framing reward outcomes in terms of losses by "fronting" a sum of money that gets lost if goals are not met, rather than providing equivalent gains for meeting goals (the economic but not psychological equivalent). Yet, despite the greater potency of losses, program administrators are often reluctant to use loss framing, perhaps because such programs can seem more punitive than organizations may wish to appear. However, it is possible to take advantage of loss aversion by designing programs in which people voluntarily put their own money at risk in the service of achieving health-behavior goals that they themselves desire. Many people enter into commercial weight loss programs and pay for a full year up front because they are overly optimistic about their chances of success. Once deposited, however, such optimism can become a self-fulfilling prophecy as loss aversion provides extra motivation to meet goals.

The combination of overoptimism and loss aversion has been used to help people lose weight by giving them the opportunity to participate in deposit contracts, in which they could deposit $0.01–$3.00 per day of their own money, with a 100% match. Participants reported their weight daily and received the sum of the deposit and the matching funds each day they were on track to meeting their monthly weight loss targets, but they forfeited both if they were not on track. The deposit contract leveraged participants' overly optimistic self-predictions of how much weight they would lose as well as loss aversion once deposits were made. In this 16-week study, average weight loss was 14.0 pounds in the deposit group compared with 3.9 pounds in the control group. This work was extended in a 32-week study in which weight loss was sustained for the duration of the intervention (8.7 vs 2.2 pounds in the control group). Although these results are promising,

to be effective as a health strategy this approach needs to achieve high ongoing participation rates to sustain its population effect. Deposit contract approaches are powerful motivators of behavior change, but they are not always popular even among those who initially opt to try them, posing a challenge to long-term success.

Peanuts Effects The prospect theory value function assumes diminishing marginal utility, which means that small gains and losses are disproportionately motivating relative to larger ones (e.g., two $500 rewards would be more potent than one $1000 reward). However, this may be too simple for small rewards (e.g., two $5 rewards may be less motivating than one $10 reward). This "peanuts effect" may be part of the reason why charities and retailers often describe costs in terms of "pennies a day." This observation challenges the expected efficacy of programs that emphasize efforts to repeatedly achieve small changes such as in weight loss programs. It is easy for a patient to rationalize that no single cigarette causes lung cancer or that no single trip to the gym prevents heart disease. If self-destructive patterns of behavior, such as cigarette smoking, weight gain, or cell phone use while driving, are seen as individual instances rather than parts of a composite whole, it is easier to understand how they can be seen as acceptable. The pleasure of smoking a cigarette or eating a dessert and the convenience and engagement of conducting business or socializing in otherwise "dead" travel time are immediate and tangible, but the marginal costs—increased risks of developing lung cancer, being overweight, or having a car accident—seem inappreciably small. Across a lifetime or a population, however, the cumulative costs and/or probabilities are not small at all.

The tendency to underweight small events can also be used to people's advantage, such as by inducing people to put away small sums for retirement savings in short cycle lengths or to make small periodic investments in their health via medication adherence. In each of these efforts, we need to think asymmetrically. In our incentive programs we should provide frequent (often daily) feedback on rewards because of present-biased preferences, but if we are *delivering* financial rewards, we want to aggregate them so that the rewards appear substantial enough to warrant attention. To use the peanuts effect to advantage, one might alert people to their rewards daily but then deliver them monthly to create larger aggregate payments.

PRESENT-BIASED PREFERENCES

Another central observation from behavioral economics is the concept of hyperbolic discounting, or "present-bias." It is standard in conventional economics to assume that people discount the future; for example, $1000 today is worth more than $1000 a year from now, since money can be invested and earn interest. However, people tend to discount outcomes that are close in time more steeply than outcomes that are farther off in time; the degree of time discounting is disproportionately greater for short time delays than for long ones, in contrast to the assumption of standard economic models.

The medical implications of present bias are profound. For example, most people would desperately like to avoid a stroke and many patients with hypertension have an understanding that taking their antihypertensive medications is one of the best ways to avoid a stroke in the future. While the classical economist would see daily adherence to antihypertensive treatment as "a good investment" to avoid a future stroke, the stroke that is avoided is far in the future and uncertain; moreover, the stroke that is prevented is never noticed. In contrast, even the relatively small effort required to stay on antihypertensive medication is immediate, continuous, and comes without any immediate compensatory benefit. To the extent that patients overly discount the future harms of a later stroke, they will be less motivated to invest today in their own medication adherence. To the classical economist, these patients are behaving irrationally because they are failing to make investments that, if they did the calculations, would clearly make them more likely to be better off; this reasoning is parallel to how classical economists consider people who undersave for retirement (the vast majority of Americans) to be irrational. To the behavioral economist, these errors are targets for therapy, in the way that we can see genetic mutations or defects in chemical pathways as therapeutic targets in the management of illness.

Present bias is somewhat subtler than simply steep discounting of the future. In fact, it reflects *two* behavioral tendencies: (1) the tendency to overweight immediate costs and benefits relative to those occurring in the future, as just discussed, and (2) the tendency to take a more evenhanded approach to *future* costs and benefits. People are much more willing to begin dieting *tomorrow*, because the overweighting of immediate costs deters us from the immediate deprivation of dieting, and the more balanced perspective on delayed deprivation makes us willing to impose these costs on ourselves in the future.

Although present-biased preferences typically promote unhealthy behaviors, policy makers can use them for beneficial effects. The motivational impact of benefits and costs, such as rewards for good behavior and punishments for bad behavior, can be increased substantially if they are made immediate. These consequences should coincide as closely as possible with the timing of the behaviors they are meant to encourage or deter. Funds for this could be provided by employers or insurers for whom this might be a cost-effective way to improve worker health and productivity.

Such programs have been shown to have dramatic effects in the area of drug addiction. This success is particularly striking, because many individuals with drug addiction already face major adverse consequences, such as loss of livelihood and disenfranchisement from their families; yet these costs are often insufficient to motivate abstinence. Similarly, small incentives offered on proof of abstinence have succeeded in tripling smoking-cessation rates where the far larger (but delayed) incentives in terms of improved health have failed. Small, daily, lottery-based incentives have significantly increased medication adherence and weight loss in part because they bring immediate rewards (money, excitement) to a situation in which the benefits of avoiding ill health are typically distant and uncertain.

Thus, rather than requiring individuals to make decisions based on consideration of their long-term best interests, it might be useful to change short-term incentives so that beneficial actions are easier and more attractive to choose. Some school districts have begun to use this approach by removing various products such as soda and candy from vending machines so that the cost of obtaining them now includes a walk off campus while healthier food and beverage options are immediately and readily available. In addition, people's willingness to commit to future changes can be leveraged by giving them choices between health-benefiting and health-harming behaviors well before they actually have to act on them. An example of this is scheduling gym visits and laboratory tests to monitor cholesterol ahead of time and having patients voluntarily accept financial penalties for last-minute cancellations in advance.

Nonlinear Probability Weighting In discussing prospect theory, we have so far discussed the concepts of reference-dependence, loss aversion, and diminishing sensitivity, collectively the properties that define prospect theory's value function (Fig. 468-1). However, prospect theory also encompasses a second important dimension: the way that people deal with—and weight—probabilities. In contrast to the standard expected utility model, which assumes that people weight outcomes according to their raw probabilities, prospect theory assumes that people overweight small probabilities but are insensitive to differences in probabilities—for example, between a 0.001 and a 0.00001 chance of winning a prize, even though the probabilities differ by several orders of magnitude—except where they provide a transition to certainty. Such overweighting of small probabilities is partly responsible for the enormous attraction of lottery tickets; yet, like present-biased preferences, this overweighting can be used to advantage in public health interventions.

Following these cognitive pathways, lottery-based reward systems have been introduced in programs aimed at motivating diverse health behaviors (described more fully below). These interventions exploit overweighting of small probabilities and also play on other psychological insights. Because people tend to be motivated by both the experience of past rewards and the prospect of future rewards, these

lottery-based systems provide frequent small payoffs and infrequent large payoffs. This approach has been demonstrated effective in a variety of areas, including helping people lose weight (52.6% of people achieve 16-week weight loss goals compared with about 10.5% in a control group) and reducing medication nonadherence (from about 23% to about 3%). However, results across studies and contexts have been inconsistent, suggesting that the active ingredients of these lottery-based incentives have not been fully elucidated.

Regret Aversion People dislike regretting decisions they have made, often voicing laments such as "If only I had …." Moreover, people are sufficiently far-sighted to anticipate possible future regret and seek to make decisions today that reduce that risk in the future. The avoidance of anticipated regret is a useful exception to present-biased preferences.

Regret aversion helps to explain the success of the Dutch postal code lottery, in which winning postal codes are selected and those living within the selected areas who purchased tickets receive prizes. Those who did not purchase tickets learn that they would have won had they done so. Individuals see their neighbors winning large prizes that they do not share, and their desire to avoid future regret drives subsequent lottery participation.

Anticipated regret has been shown to affect a variety of preventive behaviors, such as the significant increase in vaccination use among people who experienced illness after failing to get vaccinated. Lottery-based incentive programs where eligibility is conditioned on adherence (for example, you aren't eligible to play the lottery unless you had taken your medication or checked your blood pressure the previous day) can incorporate regret aversion into their design by notifying both winners and losers. Those whose number comes up but are ineligible for a reward because of nonadherence are told they would have won had they only taken their medication, checked their blood pressure, or done whatever it was the lottery program was designed to promote. Because people hate the feeling of regret, they are more likely to engage in behaviors to avoid that feeling. Indeed, the advertising campaigns of some traditional lottery systems take advantage of regret aversion. Many people play the same favorite number when the buy lottery tickets. It easy to imagine the disappointment you would feel if you missed buying a ticket one week and that was the week your favorite number came through. Advertising slogans like "don't let your number win without you" keep people in the game in order to escape that feeling of regret. The same techniques used to promote the marketing of lottery tickets can be deployed toward health promotion.

Defaults Although most of the interventions playing on behavioral economics that we have discussed so far do not qualify as "nudges," nudges remain one of the most powerful ways to influence choice. Traditional economic thinking is silent on the power of the default option—the path that is "selected" when no selection is made. However, the default bias, or status quo bias, reflects our tendency to take "the path of least resistance"—to continue doing what we have been doing, or to do what comes automatically, even when superior alternatives exist. Defaults have been blamed for a wide range of suboptimal outcomes, from the failure of employees to put aside retirement funds in companies whose default contribution rate is zero, to suboptimal allocation between investment alternatives, to excessive consumption of French fries and large sodas as part of "supersized" meals at fast-food franchises. In western European countries that have "opt-in" policies for organ donation—that is, the default is nonparticipation (as in the United States), donation rates tend to be in the range of 10%. In contrast, in countries with "opt-out" policies, in which citizens are automatically enrolled as organ donors unless they actively choose not to be, organ donation rates are often close to 99%. Defaults have been shown to increase the rate at which patients with terminal lung diseases choose comfort-oriented plans of care, and they could be used more widely to encourage the choice of beneficial health options that would vary based on the clinical context.

If used tactically, a choice architect (the person who makes decisions on how choices are presented to the end user) can utilize defaults such as changing scheduled automatic prescription refills from 30 to 90 days (or longer) for patients requiring lifelong chronic-disease therapy or changing the default option in fast-food restaurants in combination meals from large sodas to small sodas or water or french fries into carrots unless you ask for french fries to help propel people toward self-beneficial behaviors. A default toward generic prescription embedded in a health system electronic physician order system moved generic prescribing to nearly 100% in a context in which previous attempts at physician education had shown no effect at all.

Such approaches cost nothing since a default has to be set one way or another, preserve freedom of choice, and could change behavior substantially. There is little question we miss out on many opportunities to nudge people toward healthier lifestyles because we haven't considered the default option as a tactical choice to be actively incorporated into an overall health-promoting strategy.

The Rational-World Bias Perhaps the most consequential decision error affecting health-related behaviors is the tendency of public health officials and private-sector benefit designers to make policy decisions based on the assumption that people's choices are deliberative and rational. This in turn leads to assumptions that information provision is all that is needed for optimal decision-making, and that when financial incentives are offered, the amount is all that really matters.

One significant manifestation of the rational-world bias is the complexity of health insurance plans. Health insurance is complicated for many reasons, including insurance companies' desire to shield themselves from costs and, possibly, to hide or "shroud" information that might be perceived as unfavorable. The result is benefit designs with layers of rules about different forms of cost sharing for different kinds of services that vary in and out of networks. A major rationale for this complexity is to include benefit-design elements that incentivize patients to engage in specific cost-minimizing and health-maximizing behaviors across a wide range of activities. For these built-in incentives to exert their desired influence, however, patients need to understand the incentives they are facing, and there is considerable evidence that they do not. This complexity of insurance benefit design, rather than creating perfectly tailored incentives, is part of insurance design's undoing—because an incentive that can't be understood can't be effective. Most consumers lack an understanding of the most basic insurance concepts, such as deductibles, copays, and coinsurance and, when given a simplified version of a traditional insurance plan, are unable to compute the costs they would incur for basic services.

Giving a nod to the benefits of simplicity, the Affordable Care Act in the United States requires insurance plans to be presented in a standardized document that describes plan features such as premiums, deductibles, and coinsurance. However, describing something that is inherently complex in simple terms raises the risk of glossing over important subtleties. A more productive approach would be to provide consumers with a truly simplified insurance product. For example, insurers might create a plan designed with copayments only, since copayments are most easily understood by consumers: copayments are analogous to paying a price for a good or service when shopping, whereas coinsurance and deductibles make it difficult for people to estimate how much their care would cost. It is difficult, if not impossible, for a consumer to estimate 10% coinsurance on a hospital stay or an emergency room visit since they have no idea of the full amount on which the 10% will be calculated. For medical markets and patient cost-sharing elements embedded in plan design to affect decision-making *ex ante*, consumers need some way of accurately gauging not only benefits and risks of treatments but also the costs. This should occur before receiving a diagnostic test or treatment as opposed to what typically happens now: a medical bill is received after the fact.

Another manifestation of the rational-world bias is the more insidious and pervasive belief that if only people knew more about how to advance their health they would do so. This error leads to making education the centerpiece of many health interventions even though public health experts have long recognized that knowledge alone

rarely translates to health-enhancing behavior. For example, nearly everyone knows the health hazards of smoking. While raising and maintaining awareness of the dangers of smoking is an important goal, the financial budgets of the Centers for Disease Control and Prevention, or the time budgets of clinicians, might be more efficiently allocated toward efforts to change behavior that don't presume that the deficit is a lack of knowledge. Indeed, it has been argued that smokers tend to *overestimate* the hazards of tobacco, just as many women tend to *overestimate* their risks of developing breast cancer. In these cases, better or more accurate education might lead people to *lower* their estimates of risk and might, if they were perfectly rational, lead them to reduce health-promoting behaviors. In cases where the deficit is not in knowledge but in behavior, reliance on education as a primary avenue for reducing health risks may divert efforts and resources from other activities that might be much more effective.

APPLICATIONS

Weight Loss Efforts to combat obesity using incentives started in the 1970s. This early work was motivated by the observation that participants who deposited money and other valuables with a therapist and signed contracts in which return of their valuables was contingent on progress towards pre-specified goals lost tremendous amounts of weight. Even though participants received no training in weight loss or maintenance strategies, participants lost an average of 32 pounds. This small initial study lacked control groups and long-term follow-up but provided an important proof of concept.

In the first systematic study of deposit or pre-commitment contracts, participants responding to an advertisement for a weight loss program were informed that study participation required a deposit of $200 (1974 dollars), which would be fully refunded contingent on satisfactory weight loss. After an 11-session, 10-week program, those who received incentives for losing weight or for limiting calories lost significantly more weight than those who received incentives for attending sessions. Of the participants in the former two groups, 70% lost more than 15 pounds. The major limitation to this approach was that only 15% of the prospective participants who responded to the initial newspaper advertisement ended up enrolling, suggesting that deposit contracts that require participants to commit substantial funds up front are very effective for people who agree to participate, but that this requirement likely deters a substantial portion of high-risk participants from entering and its effectiveness may just as much reflect selection of those highly motivated to lose weight.

A subsequent study tested the effects on weight loss of deposit contracts of $30, $150, or $300, with the deposits returned based on either individual or group weight loss over 15 weeks. Participants in the intervention group could win $1, $5, or $10 per pound lost up to a maximum cumulative weight loss of 2 pounds per week (either individual or group average). Mean weight loss was large in all 3 groups but did not differ significantly based on contract size. However, the proportion who reached the goal of 30 pounds weight loss was significantly higher in the larger dollar groups.

Because it is increasingly difficult to shed pounds as weight is lost, the investigators also tested whether a deposit contract with increasing payments ($5, $10, $20, $40, $75) for each 5-pound increment of weight loss would be more effective than offering $30 for each 5-pound increment of weight loss. Participants in both conditions were also offered a maintenance program requiring a $100 deposit, returned in $25 increments for attendance at follow-up visits every 3 months. The increasing contract resulted in qualitatively larger weight loss during the weight loss phase, but the maintenance program did not prevent weight re-gain, likely because the magnitude of the deposit contract for maintenance was small, and feedback was infrequent (only every 3 months).

Paying participants for weight loss using direct payments was less effective than deposit contracts. In a randomized trial, cash payments up to $25 per week for making 100% of proportional progress toward goal, $12.50 for 50% of goal, and $2.50 for not gaining weight did not result in greater weight loss in the payment group than among control subjects.

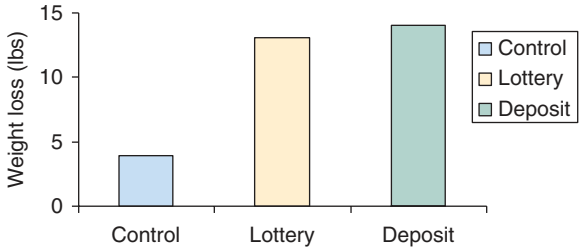

FIGURE 468-2 Weight loss in incentives versus control. *(Figure created using data from KG Volpp et al: Financial incentive-based approaches for weight loss: A randomized trial. JAMA 300:2631, 2008.)*

Studies that have shown no effects on either initial weight loss or maintenance typically have used incentives of small magnitude or were targeted at behaviors, like attendance at weight loss programs that, by themselves, do not ensure weight loss. In recent years, weight loss incentives have become a common feature in programs used by employers and health plans and a variety of start-ups like *stickk.com* and *dietbet.com* use deposit contracts as a way of trying to help people lose weight.

Newer approaches have provided proof of concept that daily lottery-type incentives and precommitment contract incentives promote initial weight loss over 16 weeks (lottery = 13.1 lbs; $p = .014$ for lottery vs control; deposit contract = 14.0 lbs; $p = .003$ vs control; **Fig. 468-2**). However, participants regained most of the weight they had lost over the following 3 months. Longer trials (8 months) found no difference in effectiveness of deposit contracts for continuous 8-month weight loss versus 6-month weight loss with 2 months of maintenance, but both were successful in achieving a mean weight loss of about 10 pounds. Subsequent tests included an employer-based study showing greater effectiveness of team competitive versus individual incentives, although there was a confound in that participants in the teams had the potential to win more money than those in the individual arms.

While both of these studies suggest that financial incentives promote weight loss, many employers use premium adjustments (increases or decreases to health insurance payments) as their standard approach to using financial incentives for health promotion. The effectiveness of premium-based financial incentives to promote weight loss has been assessed in a workplace wellness program and with a goal of losing 5% of initial weight over the next year. Participants were randomly assigned to a control group with no other intervention or one of three financial incentive groups. Two intervention groups were offered a premium reduction of $550 if they achieved their weight loss goal by 1 year. The "delayed" group would receive the premium adjustment in the following year, spread across each pay period. The "immediate" group would have their premiums adjusted as soon as the weight loss goal was met. A third intervention group was offered a daily lottery with about a 1 in 5 chance of winning $10 and a 1 in 100 chance of winning $100. To be eligible to win each day, participants had to weigh in and be on track to lose 5% of their initial weight loss by 6 months, with maintenance for the subsequent 6 months. After 1 year in the program, none of the intervention approaches showed a significant degree of weight loss. The control group gained <0.1kg.

The relative ineffectiveness of premium-based financial incentives is not surprising given their design. Premium adjustments are logistically appealing because the infrastructure to do so is already in place, but the evidence for their effectiveness in on the negative side of unknown and theory argues against it. Such incentives are typically hidden in paychecks that are directly deposited in bank accounts and may go unnoticed by the individual. While a $550 incentive seems like a large amount, it is only $20 in each biweekly paycheck. Typically, these incentives are administered on an all-or-nothing basis contingent on meeting a specific threshold such as a body mass index of ≤25 kg/m^2, meaning that those who are close to that target may be motivated by a goal within reach, but those who are farther away (and have the most weight to lose and the most health to gain) may be less motivated

(perhaps even demotivated) by a goal that doesn't seem attainable. The best evidence and theory now suggests that the standard approach of using premium-based incentives is not that effective and that employers should consider alternative delivery channels for financial incentives to promote health.

A common problem employers and health plans struggle with is getting high levels of engagement among employees/health plan members. Weight Watchers, the largest commercial weight loss program in the United States, worked with a team of academic investigators to conduct a randomized controlled trial involving more than 23,000 participants testing the impact of offering employer subsidization of Weight Watchers membership fees of 50%, 80%, 100% or 50% that could turn into 100% conditional on attending at least 3 Weight Watchers classes a month. Higher subsidies led to higher program enrollment ($p<.0001$). Enrollment differed significantly by subsidy level ($p<.0001$). The 100% subsidy produced the highest enrollment (7.7%), significantly higher than each of the lower subsidies (vs 80% subsidy: 6.2%, $p = .002$; vs 50% subsidy: 3.9%, $p<.0001$; vs hybrid: 3.7%, $p<.0001$). Enrollment in the 80% subsidy group was significantly higher than both lower subsidy groups (vs 50% subsidy: 3.9%, $p<.0001$; vs hybrid: 3.7%, $p<.0001$). Among enrollees, there were no differences among the four groups in attendance or weight loss. In all groups overall weight loss was modest, with a mean weight loss of 2.6 pounds (95% confidence interval [CI], 5.7-lb loss to 0.3-lb gain) in the 100% subsidy arm; 1.5 pounds (95% CI, 5.6-lb loss to 1.3-lb gain) in the 80% subsidy arm; 3.8 pounds (95% CI, 7.9-lb loss to 0.4-lb gain) in the 50% subsidy arm, and 4.0 pounds (95% CI, 8.1-lb loss to 0.1-lb gain) in the hybrid subsidy arm. In all arms, attendance rates drop steadily over time, suggesting that while the hypothesized tradeoff between higher subsidies and lower ongoing engagement in the program did not exist, ongoing participation is a challenge across the board and subsidies that lower the cost of participating are insufficient to achieve high levels of ongoing engagement **(Fig. 468-3)**.

In another study, 281 overweight and obese adults were randomly assigned to a control group or one of three incentive groups for a 13-week physical activity program. All participants were given a goal of achieving 7000 steps a day, tracked automatically using their smart phones. Participants in each of the three incentive arms were offered the same magnitude incentive, $1.40 per day, and were told that accumulated earnings would be sent via a check at the end of each month. However, the incentive in each group was framed differently. In the standard gain incentive group, participants were told that they could earn $1.40 each day they achieved the goal. In the regret lottery incentive group, participants were in a daily regret lottery in which they had an 18 in 100 chance of winning $5 and a one in 100 chance of winning $50, which averages to $1.40 per day. In the loss framing incentive group, participants were told at the beginning of each month that $42 had been placed in a virtual account and that they would lose $1.40 each day the goal was not achieved. During the 13-week intervention, participants in the control, standard gain, and regret gain arms achieved their daily step goal about 30%, 35% and 36% of the time, respectively, but those gain-framed incentive arms were not significantly different from control. However, in the loss framing group, participants achieved the goal 45% of the time, a 50% relative increase, which was significantly greater than the control arm ($p = .001$). This study demonstrated how loss framing can be used to motivate behavior change. It is also one of the first studies to create a loss frame without requiring participants to put their own money at risk using a deposit contract. This is important because fewer people are willing to engage in deposit contract-based incentives than reward-based incentives.

Experience with behavioral economics and weight loss provides several general lessons that are transferable to other health applications. While early studies largely emphasized research in the size of financial incentives, later studies have revealed that the design of the incentive strategy is at least as important. Moreover, designs can vary considerably based on the timing of incentives that can be immediate or delayed, or frequent or one time; the setting of targets that can be achievable, aspirational, or demotivating; the certainty of incentives that can be fixed or probabilistic; the channel for incentives that can either be delivered separately or bundled through payrolls; or the framing of incentives as gains or losses. Classical economists would see only the size of the incentive as an available lever for motivation, but behavioral economists face a much larger set of considerations in designing and testing effective therapies.

Medication Adherence Numerous studies have shown that at least a third of patients fail to adhere to medication regimens. One approach to improving medication adherence is to change some of the underlying defaults by, for example, using 90-day prescriptions for chronic illness medications as opposed to 30-day prescriptions. While we are unaware of empirical evidence supporting longer prescription cycles, it seems logical that adherence rates would be higher over a year if people had to get refills three times as opposed to 11 times—the latter provides more opportunities to forget, experience delays, or fall off the wagon. Automatic refills through prescription mail order might similarly prevent some people from inadvertently falling off the wagon

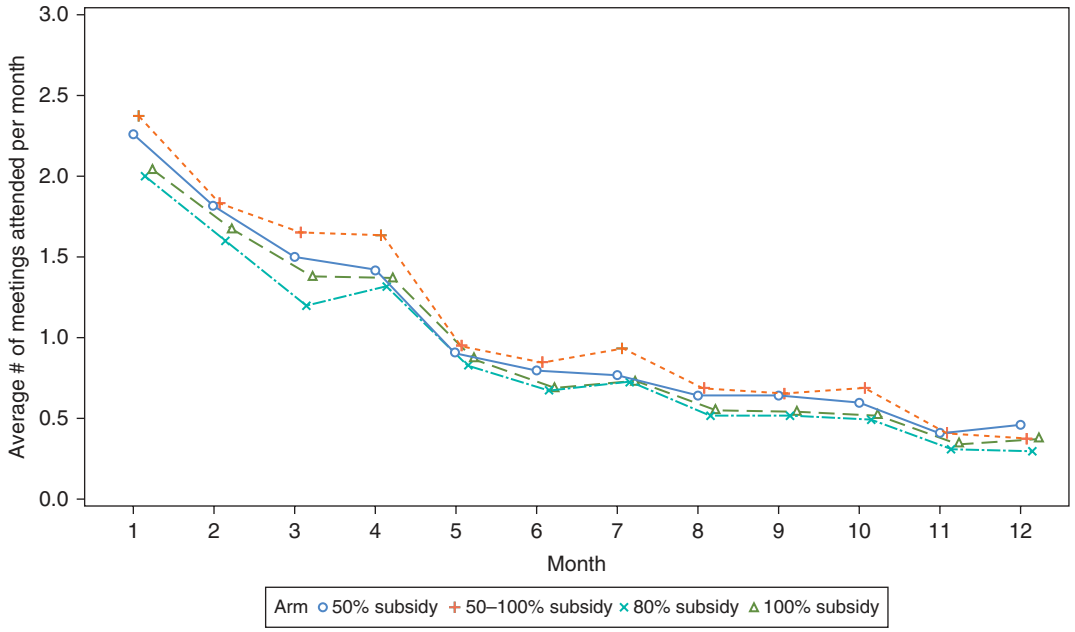

FIGURE 468-3 Attendance rates at Weight Watchers over time in different subsidy groups. *(From LK John et al: "The effect of cost sharing on an employee weight loss program": A randomized trial. Am J Health Promot 32:170, 2018.)*

of medication adherence, giving them one less thing to think about, or fail to think about.

Ninety-day prescriptions or automatic refills could be set up as the default and patients or their providers could opt out if desired. Of course, opt-out defaults are not always possible. A large pharmacy benefits manager wanted to encourage automatic refills for patients on long-term medication but could not have members opt out of such a system because of the potential that those who missed the implications of the opt-out would be surprised or angry about finding credit card charges for automatic refills. In some non-health settings, marketers have used a process sometimes called "active choice" to force explicit consideration of alternatives. Often when ordering airline tickets online the sale cannot proceed unless you affirmatively accept or reject the offer to buy travel insurance. In those settings, the requirement is often seen as a nuisance, particularly if the offer is perceived as a way to cross sell an otherwise unwanted insurance product.

But the same principles can be applied in more health promoting and prosocial settings. Switching from an opt-in system to embedding a choice (yes or no) within the prescription refill process and highlighting the advantages in terms of convenience ("we can send your refills to you automatically or you can get your refills manually if you prefer") resulted in more than twice as many patients choosing to be in the automatic-refill program.

A feature of many health insurance plans is that they require patients to pay some costs out-of-pocket, and hence discourage the use of a number of high-value elements of care, such as the treatment of hypertension or the use of statins by patients with diabetes—care that is widely seen as worth its cost. Support for the use of health insurance deductibles that require patients to have "skin in the game" for their health expenditures derives from insurance theory as well as the seminal RAND health insurance experiment, which demonstrated that these deductibles help overcome moral hazard and reduce the consumption of health care services. Copayments, deductibles, and other out-of-pocket costs make consumers more cost conscious and so aim to make them better shoppers for health care services. Indeed, the rise of high deductible health plans largely aims to increase patients' skin in the game, to make them more value-conscious shoppers.

However, while deductibles and copayments make sense as a way to reduce overutilization of some lower-value health care services, deductibles and copayments make considerably less sense when patients receive medications to manage their hypertension, diabetes, or hyperlipidemia. Given that deductibles and copayments are designed to reduce utilization, why would we ever want to apply them to antihypertensives or statins or insulin given the high health value of these drugs? Why put any barriers between patients and these drugs? Indeed, as the RAND health insurance study showed high-deductible health plans are as likely to discourage the use of high-value services as the use of low-value services. Because patients lack knowledge about what tests or services are of high or low value, and do not have information about the relationship between price and quality, such plans discourage spending on *all* tests and services, including those of high value.

Value-based insurance design—which involves discounting, or making free, services that are deemed to be high in value—is an attempt to sharpen the blunt incentives inherent in deductibles and copayments. Value-based insurance design was inspired by research that showed the use of higher copayments significantly reduced the use of services such as prescriptions but ultimately raised costs, because lower rates of medication nonadherence led to higher rates of emergency department visits and adverse outcomes. Extrapolating from these results, it was natural to conclude that lowering cost sharing for high-value activities, such as taking medications for chronic conditions, would increase adherence and potentially thereby reduce costs. The Affordable Care Act incorporates a kind of value-based insurance design in its requirement that preventive services be offered to patients at no charge.

Unfortunately, value-based insurance design has not delivered on the hope that it would both save money and improve health. From the perspective of the purchaser (for example, the employer or insurer) the economic impact of value-based insurance design depends on whether it can make enough people adherent who were previously nonadherent—and on the health and cost consequences of that improved adherence—to offset the loss of the copayments from those who were already adherent. Although some experimental tests of value-based insurance design have found that copayment reductions increase adherence, those effects have typically been small, in the range of 3–6 percentage points. Even among patients who had recent heart attacks and were given their cardiovascular medications for free, average adherence was only about 45%, just a few percentage points higher than that seen with regular copayments. One reason for these disappointing results is the "dog that didn't bark" problem. People who are nonadherent don't notice that their copays have been reduced because they aren't using (and thus aren't paying for) the service.

Indeed, one of the valuable lessons learned from efforts to introduce value-based insurance design has been a reminder of the asymmetry of the forces that surround patient engagement. Based on conventional economic thought, it might seem reasonable to assume that decreasing copayments would create effects equal and opposite to those of increasing copayments. However, behavioral economic research reveals that framing matters and that losses (in this case, higher copayments intended to reduce use) loom larger in patients' minds than gains (lowered copayments). Furthermore, people who would be deterred by higher copayments are different from people who might become adherent with lower copayments, because the first group consists of those who take their medications while the second group consists of those who do not. Behavioral economic thinking, therefore, helps to explain what has been observed: Increases in copayments have larger effects in reducing adherence than decreases in copayments have in raising adherence. In general, copayment increases lead to far smaller decreases in medication adherence than copayment decreases lead to increases in medication adherence.

Value-based insurance design is an appealing idea. But its benefits could be increased through the application of ideas from behavioral economics, such as simple changes in reward delivery to increase salience (e.g., retaining the copay, but sending a rebate) and communications from insurers to patients so that even those who are nonadherent are aware of the benefit. Better designs might also reflect that most medication adherence happens at least daily, and so reinforcements to that behavior probably need to occur more frequently than the 30- or 90-day cycles coinciding with prescription refills.

A series of studies have used daily lottery-based financial incentives to improve medication adherence. Early work tested the impact of a lottery on medication adherence among patients on warfarin. Participants were eligible for the lottery daily if they correctly took their warfarin the day before. In the first study where the lottery had an expected value (EV) of $5 per day, the proportion of incorrect pill taking was 2.3% (97.7% adherence), compared with a historic mean of 22% incorrect pill taking in this clinic population. In the second study (EV of $3 per day), the overall mean adherence was 98.4% (1.6% days nonadherent), similar to the $5/day study. In a two-arm randomized trial of lotteries for warfarin adherence, the *a priori* subgroup with baseline international normalized ratios (INRs) below the therapeutic range showed no change relative control, but in the a priori subgroup with out-of-range INRs there was a significant reduction in out-of-range INR in the lottery arm vs the control arm (adjusted odds ratio, 0.39; 95% CI, 0.25–0.62). This study highlighted the importance of targeting nonadherent patients in terms of interventions and provided evidence from a randomized, controlled trial (RCT) that lottery incentives can be effective in achieving improved clinical outcomes.

A four-arm NHLBI-funded RCT tested the impact of daily lotteries and daily reminders in a 2 × 2 factorial design on warfarin adherence to address the question of the degree to which a daily lottery is effective due to the fact it also constitutes a daily reminder. However, this study found that while participants in the reminder group had the lowest percentage of time out of target INR range, with an adjusted odds of an out-of-range INR 36% lower than among those in the control group (95% CI, 7–55), the only group with significant improvement in incorrect adherence was the lottery group (incorrect adherence: 12.1% compared with 23.7% in the control group; difference of 7.4%; 95% CI,

–14 to –0.3). There was no relationship between changes in adherence and anticoagulation control in the lottery group, highlighting that participants may appear to change their behavior without perhaps taking the medication, highlighting the importance of serologic or biometric confirmation when possible.

The 5000 Hours Problem A major challenge is determining the optimal method to reach patients and reinforce their behavior each day if we want to significantly improve medication adherence. Even patients with chronic illnesses may spend only a few hours a year with a doctor or nurse, but they spend about 5000 waking hours a year doing just about everything else. Those 5000 hours are when they live their lives and make choices about what to eat and whether to exercise, smoke, take their medications, or visit the doctor.

Although what people do in those hours almost certainly affects their health outcomes, the hours are typically ignored by the U.S. health care system, in part because current approaches to U.S. health care financing support health care during visits to the doctor, not between them, and because "hovering over" people during the hours between visits is personnel-intensive, often requiring nurses or other clinicians to call or visit patients or to staff telemedicine programs. Hovering also requires a fair amount of the very kind of engagement in their own health and health care that is so often missing in the patients these interventions aim to reach. As a result, many of the most promising efforts in telemedicine and home health care have been disappointing.

If some form of hovering is required to engage people who are otherwise hard to engage during the 5000 hours, it almost certainly has to become substantially more automated—both because providers must reduce the need for expensive personnel and because patients have in many cases already revealed limits to their willingness to exert themselves to improve their health. Nevertheless, there is reason for optimism based on the increasing use of cell phones and other wireless devices that make it technologically easier to embed reminders and other forms of touch into patients' lives. Indeed, one key lesson from behavioral economics is that rather than trying to change people's behavior patterns to promote health, it is better to restructure their environment and circumstances so that their existing behavior patterns are more likely to lead to better outcomes. Those efforts require a substantial amount of hovering over patients. Cell phones and other wireless devices don't necessarily change behavior on their own, but because they are already part of many patients' everyday lives they allow previously private behaviors to be witnessed and at times acted upon.

Indeed, an error in early approaches to technology and health behavior overgeneralized from the technologies that support the "quantified self" movement. Apps and wearables that track your diet, physical activity, and biometrics were largely designed for people passionate about measuring themselves. Such individuals don't need a lot of encouragement to wear devices or enter data. The same approaches are far less likely to be useful for patients with difficult-to-manage chronic illness. Many of the internal and external challenges that make their chronic illness hard to manage also make such monitoring hard to manage. A patient who is nonadherent to medication is likely also to be nonadherent to using a new electronic device, but devices like cell phones that are already in use, or other devices that require much less active involvement (like wireless pill bottles) offer more conceptual appeal.

Patients with poorly controlled diseases typically exhibit multiple risk behaviors: poorly controlled diabetes, for example, can be exacerbated by poor diet, lack of exercise, obesity, and medication nonadherence. In testing daily use rates of wireless glucometers and blood pressure cuffs within a population of patients with poorly controlled blood sugars within a health system population, patients who were randomized to be asked to use their wireless glucometer or blood pressure cuff daily used these devices only 50% of the time by the end of 3 months, whereas patients randomized to receive daily lotteries conditional on device use used their devices more than 80% of the time and achieved better glycemic control.

FUTURE PERSPECTIVES

Human health derives from the interaction of basic biologic processes, environmental exposures, social structures, and behavior. The field of behavioral economics has greatly contributed to our understanding of behavior and has made significant contributions to the science of public policy. Given that understanding, we have the opportunity to replace older policies based on unrealistic normative models of rational decision-making with newer policies reflecting our most up-to-date understanding of how humans actually make decisions. Individual and population health outcomes would be very different if people were able to weigh the present and future costs of their actions carefully and dispassionately and had the necessary information and self-control to implement behavioral plans and overcome decision errors that contribute to unhealthy behaviors. Because few people can meet any of those challenges, let alone all, we should not structure our behavior change interventions and public health policies around such models of behavior.

There is broad potential for using understanding of human motivation rooted in behavioral economics to improve private and public approaches to health behavior. One major question is whether developed economies will continue to invest the majority of their health care dollars in treatment (typically about 97% of health care dollars) rather than shifting it toward innovations that seek to keep people healthy. This will be particularly important in settings where treatment options are limited and highly effective methods of prevention exist. For example, it has been estimated that a combination of low-cost cardiovascular drugs could reduce cardiovascular events by 62–88% with perfect adherence, revealing that reducing atherosclerotic cardiovascular disease risk is largely a *behavioral* challenge, given that adherence to medications remain low despite effective pharmacologic solutions. Shifts in health care financing away from fee-for-service toward various forms of payment that require health delivery systems to take on financial risk for populations of patients may drive greater interest in addressing these behavioral and social determinants of health. Research expenditures, which in many developed countries are also roughly allocated about 97% to new treatments and about 3% to prevention, similarly could be shifted to focus more on testing of innovative approaches to improve population health.

The same errors that misdirect patients and providers also misdirect policy makers. In part because of present bias, preventive services often are covered by insurance only if they show a positive return on investment, and yet treatments of existing disease are not held to the same standard. An employer wondering whether to introduce a smoking cessation program for employees wonders about the return on that investment in terms of reduced illness and its cost. The same employer might never question the return on investment of treating lung cancer in the same employee pool, despite what would almost certainly be a negative return on investment. These asymmetries are so embedded in policy making as to be nearly invisible or at least unchallengeable. In fact, the cost of treatments is not even allowed to be considered in Medicare coverage decisions. This prohibition naturally leads to overinvestment in treatments of low value and underinvestment in prevention. The same standard for assessing the impact of health programs, with the goal of achieving the most health possible with the available resources, should be used for both preventive and therapeutic services.

Despite the promise of behavioral economics in structuring policy solutions to social goals, plenty of existing policies that have nothing to do with behavioral economics are effective. For example, raising taxes on cigarettes and other unhealthy goods where it is in the public interest to consume less is a powerful policy tool derived from classical economics. Indeed, tobacco taxes represent one of the most effective ways to curb the use of tobacco and its initiation among youth. Behavioral economics can help make such policies more effective but should not be seen as a substitute for them.

For private-sector entities, the implications of choosing defaults wisely are recognized by many organizations that aim to shift the "path of least resistance" towards healthier choices. Setting up defaults in benefit program design to favor health plans that provide better coverage of preventive services, changing the environment in workplaces to make it easier to take the stairs, and serving more healthful food in cafeterias represent approaches to gently lead people toward individual and population goals.

While medical research continues to generate new tests, interventions, and drugs successfully targeting conditions recently seen as intractable, even the most effective drugs will not work if physicians fail to prescribe them and if patients fail to take them. Although the dominant forms of investigation in medicine seek cellular or molecular therapeutic targets to modify disease, behavioral sciences have revealed cognitive pathways that operate nearly as predictably as the genetic code. The opportunity for behavioral economics to improve health and health care delivery derives from its recognition of these behavioral pathways and the growing empirical evidence about how to best make use of them.

469 Complementary, Alternative, and Integrative Health Approaches

Josephine P. Briggs

The search for health includes many beliefs and practices that are outside conventional medicine. Physicians are important sources for information and guidance about health matters, but our patients also rely on a wide range of other sources including family and friends, cultural traditions, alternative practitioners, and increasingly the Internet, popular media, and advertising. An important step in patient-centered care is understanding what patients are doing to manage their health. This understanding is important to harness potential benefits and to help patients avoid harm.

DEFINITIONS AND SCOPE

Complementary health approaches include a broad range of practices, interventions, and natural products, which are not typically part of conventional medical care, or which may have origins outside of usual Western practice. *Complementary* approaches are defined as those used together with conventional therapies, distinguishing them from *alternative* practices, those used as a substitute for standard care. Complementary practices can roughly be divided into two major groups—mind and body practices, and natural products. Mind and body practices and disciplines are usually administered by or taught to others by a clinician, trained practitioner, or teacher, and include acupuncture, massage, meditation, and hypnosis. Natural products include a diverse group of orally or topically administered substances such as botanical products, unconventional diets, dietary supplements, herbal medicines, homeopathic remedies, probiotics, and others. Brief definitions for some of the common complementary and alternative health practices are provided in **Table 469-1**. Although some complementary health practices are recommended or provided by a physician or a complementary health care provider such as a chiropractor, acupuncturist, or naturopathic practitioner, many of these practices are undertaken as "self-care." Although some are reimbursed, most are paid for out of pocket.

In the last decade or so, the terms *integrative health care* and *integrative medicine* have entered the dialogue. The term *integrative health* care emphasizes a holistic, patient-focused approach to health care and wellness. Most integrative health care is team-based, often bringing conventional and complementary approaches together with self-care in a coordinated way. Physicians advocating this approach generally included selected complementary health practices in the care they offer patients, and many have established practice settings that include complementary health practitioners. Integration of select complementary approaches is common in Veterans Administration and Department of Defense facilities, particularly as part of management of pain and post-traumatic stress disorder. A 2007 national survey conducted by the Centers for Disease Control and Prevention's National Center for Health Statistics found that 42% of hospices had integrated complementary health practices into the care they provide. Although the integrative approach appears to be attractive to many patients, the heavy use of dietary supplements and the weaknesses in the evidence base for a number of the interventions offered in integrative practices continue to attract substantial concern and controversy.

Until a decade ago or so, *complementary and alternative medicine* could be defined as practices that are neither taught in medical schools nor reimbursed, but this definition is no longer workable, since medical students increasingly seek and receive some instruction about complementary health practices, and some practices are reimbursed by third-party payers.

By its nature, the demarcation between mainstream medicine and complementary health practices is porous, varying from culture to culture and over time. Traditional Chinese medicine and the Indian practice of Ayurvedic medicine were once the dominant health teachings in those cultures. Certain health practices that arose as challenges to the mainstream have been integrated gradually into conventional care. Examples include the teachings of Fernand Lamaze that led to the widespread use of relaxation techniques during childbirth, the promotion of lactation counseling by the La Leche League, and the teaching of Cicely Saunders and Elizabeth Kübler-Ross that established the hospice movement.

The late nineteenth century saw the development of a number of healing philosophies by care providers who were critical of the medicine of the time. Of these, naturopathy and homeopathy, which arose in Germany, and chiropractic and osteopathy, which developed in the United States, have endured. Osteopathic medicine is currently thoroughly integrated into conventional medicine, although the American Medical Association (AMA) labeled it a cult as late as 1960. The other three traditions have remained largely separate from mainstream medicine, although chiropractic care is increasingly available in some conventional care settings.

PATTERNS OF USE

The first large survey of use of these practices was performed by David Eisenberg and associates in 1993. It surprised the medical community by showing that >30% of Americans use complementary approaches. Many studies since that time have extended those conclusions. The National Health Interview Survey (NHIS), a large, national household survey of health practices conducted by the National Center for Health Statistics, a component of the Centers for Disease Control and

TABLE 469-1 Terminology of Complementary Health Approaches	
Mind and Body Practices	
Acupuncture and acupressure	A family of procedures involving stimulation of defined anatomic points, a component of the major Asian medical traditions; most common application involves the insertion and manipulation of thin metallic needles
Alexander technique	A movement therapy that uses guidance and education to improve posture, movement, and efficient use of muscles for improvement of overall body functioning
Guided imagery	The use of relaxation techniques followed by the visualization of images, usually calm and peaceful in nature, to invoke specific images to alter neurologic function or physiologic states
Hypnosis	The induction of an altered state of consciousness characterized by increased responsiveness to suggestion
Massage	Manual therapies that manipulate muscle and connective tissues to promote muscle relaxation, healing, and sense of well-being
Meditation	A group of practices, largely based in Eastern spiritual traditions, intended to focus or control attention and obtain greater awareness of the present moment, or mindfulness
Reflexology	Manual stimulation of points on hands or feet that are believed to affect organ function
Rolfing/structural integration	A manual therapy that attempts to realign the body by deep tissue manipulation of fascia
Spinal manipulation	A range of manual techniques, employed by chiropractors and osteopaths, for adjustments of the spine to affect neuromuscular function and other health outcomes
Tai chi	A mind and body practice originating in China that involves slow, gentle movements and sometimes is described as "moving meditation"
Therapeutic touch	Secular version of the laying on of hands, described as "healing meditation"
Yoga	An exercise practice, originally East Indian, that combines breathing exercises, physical postures, and meditation
Traditional Medical Systems	
Ayurvedic medicine	The major East Indian traditional medicine system; treatment includes meditation, diet, exercise, herbs, and elimination regimens (using emetics and diarrheals)
Curanderismo	A spiritual healing tradition common in Latin American communities that uses ritual cleansing, herbs, and incantations
Native American medicine	Diverse traditional systems that incorporate chanting, shaman healing ceremonies, herbs, laying on of hands, and smudging (ritual cleansing with smoke from sacred plants)
Siddha medicine	An East Indian medical system (prevalent among Tamil-speaking people)
Tibetan medicine	A medical system that uses diagnosis by pulse and urine examination; therapies include herbs, diet, and massage
Traditional Chinese medicine	A medical system that uses acupuncture, herbal mixtures, massage, exercise, and diet
Unani medicine	An East Indian medical system, derived from Persian medicine, practiced primarily in the Muslim community; also called "hikmat"
"Modern" Medical Systems	
Anthroposophic medicine	A spiritually based system of medicine that incorporates herbs, homeopathy, diet, and a movement therapy called eurythmy
Chiropractic	Chiropractic care involves the adjustment of the spine and joints to alleviate pain and improve general health; primarily used to treat back problems, musculoskeletal complaints, and headaches
Homeopathy	A medical system with origins in Germany that is based on a core belief in the theory of "like cures like"—compounds that produce certain syndromes, if administered in very diluted solutions, will be curative
Naturopathy	A clinical discipline that emphasizes a holistic approach to the patient, herbal medications, diet, and exercise; practitioners have degrees as doctors of naturopathy
Osteopathy	A clinical discipline, now incorporated into mainstream medicine, that historically emphasized spinal manipulative techniques to relieve pain, restore function, and promote overall health

Prevention, has addressed the use of complementary health practices in 2002, 2007, and 2012. The NHIS survey uses methods that create a nationally representative sample and has a sample size large enough to permit valid estimates about some subgroups. Information was obtained from 31,000 adults in 2002; 23,300 adults and 9400 children in 2007; and 34,500 adults and 10,200 children in 2012. In all three surveys, approximately one-third of adults report using some form of complementary therapy or health practice. In the 2012 survey, 32.2% of adults and 11.6% of children had used one or more modalities. These surveys yield the estimate that nonvitamin, nonmineral dietary supplements are used by ~18% of adults and 5% of children. The most prevalent mind and body practices are yoga, chiropractic or osteopathic manipulation, meditation, and therapeutic massage. Americans are willing to pay for these services; the estimated out-of-pocket expenditure for complementary health practices in 2012 was $30.2 billion ($28.3 billion for adults and $1.9 billion for children), representing 1.1% of total health expenditures and 9.2% of out-of-pocket costs.

The appeal of unproven complementary health approaches continues to perplex many physicians. Many factors contribute to these choices. In NHIS surveys, the most common reason cited for use of complementary health approaches is the management of pain. In one analysis of data from the 2012 NHIS survey, >40% of people with a musculoskeletal pain disorder used a complementary health approach. This was significantly higher than use by people without a musculoskeletal pain disorder (24%). Some patients seek out complementary health practitioners because they offer optimism or greater personal attention. For others, alternative approaches reflect a "self-help" approach to health and wellness or satisfy a search for "natural" or less invasive alternatives, since dietary supplements labelled as natural are believed, often incorrectly, to be inherently healthy.

PRACTITIONER-BASED DISCIPLINES

Licensure and Accreditation At present, six fields of complementary health practice—osteopathic manipulation, chiropractic, acupuncture and traditional Chinese medicine, therapeutic massage, naturopathy, and homeopathy—are subject to some form of educational accreditation and state licensure. Accreditation of educational programs is the responsibility of professional organizations or commissions under federal oversight by the Department of Education. Licensure, in contrast, is strictly a state matter, generally determined by state legislatures. Legal recognition establishes public access to therapies even when there is no scientific consensus about their clinical value.

Osteopathic Manipulative Therapy Founded in 1892 by the physician Andrew Taylor Still, osteopathic medicine was originally based on the belief that manipulation of soft tissue and bone can

correct a wide range of diseases of the musculoskeletal and other organ systems. Over the ensuing century, the osteopathic profession has welcomed increasing integration with conventional medicine. Today, the postgraduate training, practice, credentialing, and licensure of osteopathic physicians are virtually indistinguishable from those of allopathic physicians. Osteopathic medical schools, however, include training in manual therapies, particularly spinal manipulation.

Chiropractic The practice of chiropractic care, founded by David Palmer in 1895, is the most widespread practitioner-based complementary health practice in the United States. Chiropractic practice emphasizes manual therapies for treatment of musculoskeletal complaints, although the scope of practice varies widely, and in some rural areas, chiropractors may serve a primary care role, due in part to the lack of other providers. According to the NHIS, ~8% of American adults and 3% of children receive chiropractic manipulation in a given year.

Since the mid-1970s, chiropractors have been licensed in all 50 states and reimbursed by Medicare. Chiropractic educational standards mandate 2 years of undergraduate training, 4 years of training at an accredited school of chiropractic, and in most states, successful completion of a standardized board examination. Postgraduate training is not required. The U.S. Department of Labor estimates that there are 45,000 licensed chiropractors (2015 figure). There is substantial geographic variation, with greater numbers of practitioners and greater use in the midwest, particularly in rural areas, and lower use in the southeast.

Historically, the relationship between the medical and chiropractic professions has been strained. Extending through the 1970s, the AMA set forth standards prohibiting physicians consulting or entering into professional relationships with chiropractors, but in 1987, after a decade of complex litigation, the U.S. District Court found the AMA in violation of antitrust laws. An uneasy truce has followed, with continued physician skepticism, but also evidence for robust patient demand and satisfaction.

The role of both osteopathic and chiropractic spinal manipulative therapies (SMTs) in management of low-back pain has been the subject of a number of carefully performed trials and many systematic reviews. Conclusions are not consistent, but the most recent 2017 guidelines from the American College of Physicians on noninvasive treatments for acute, subacute, and chronic low-back pain conclude that spinal manipulation has a small effect on improving function and pain compared with control—either a sham manipulation or an inert treatment. Although evidence for spinal manipulation for chronic low-back pain is graded as *low-quality*, the recommendation for consideration of nonpharmacologic treatment including spinal manipulation is graded as a *strong recommendation*, reflecting increasing concern with the impact of chronic opioid use for low-back pain.

The evidence of benefit of spinal manipulation for neck pain is not as extensive, and continued concern that cervical manipulation may occasionally precipitate vascular injury clouds a contentious debate.

Naturopathy Naturopathy is a discipline that emerged in central Europe in the nineteenth century as part of the Natural Cure movement and was introduced to the United States in the early twentieth century by Benjamin Lust. Nineteen states and the District of Columbia currently license naturopathic physicians, with considerable variation in the scope of practice. The naturopathic profession is actively seeking licensure in other states. There are estimated to be ~5000 licensed naturopathic physicians in the United States. There is also a robust naturopathy presence in Canada. Conventional and unconventional diagnostic tests and medications are prescribed, with an emphasis on relatively low doses of drugs, herbal medicines, healthy diet, and exercise. While there is some support for success of naturopathic practitioners in motivating healthy behaviors, concern exists about the heavy promotion of dietary supplements, most with little rigorous evidence.

Homeopathy Homeopathy was widespread in the United States in the late nineteenth and early twentieth centuries and continues to be a common alternative practice in many European countries, but estimates from the NHIS suggest that <2.2% of Americans visit a homeopathic practitioner in any given year. In the United States, licensure as a homeopathic physician is only possible in three states (Arizona, Connecticut, and Nevada) where it is restricted to licensed physicians. The number of practitioners is uncertain, however, because some states include homeopathy within the scope of practice of other fields, including chiropractic and naturopathy, and some practitioners may self-identify as homeopathic practitioners. As discussed below, the regulatory framework for homeopathic remedies differs from other dietary supplements. Homeopathic remedies are widely available and commonly recommended by naturopathic physicians, chiropractors, and other licensed and unlicensed practitioners.

Therapeutic Massage The field of therapeutic massage is growing rapidly, as use by the public is increasing. According to U.S. Department of Labor statistics, there are ~168,000 licensed massage therapists employed in the United States, and by 2024, this number is projected to grow by 22%. Forty-five states and the District of Columbia currently have laws regulating massage therapy; however, there is little consistency, and in some states, regulation is by town ordinance. States that do provide licensure for massage therapists typically require a minimum of 500 h of training at an accredited institution, as well as meeting specific continuing education requirements and carrying malpractice insurance. Massage training programs generally are approved by a state board, but some may also be accredited by an independent agency, such as the Commission on Massage Therapy Accreditation (COMTA). The development of regulatory standards for therapeutic massage has not yet caught up with the evolution of the field or the high demand. Many techniques used are also employed by physical therapists.

Acupuncture and Traditional Chinese Medicine A venerable component of traditional Chinese medicine, with a history of use that extends at least 2000 years, acupuncture became better known in the United States in 1971, when *New York Times* reporter James Reston wrote about how doctors in China used needles to ease his pain after surgery. More than 3 million adults in the United States use acupuncture, according to NHIS data. In a number of European countries, acupuncture is performed primarily by physicians. In the United States, the training and licensure processes for physicians and nonphysicians differ. Currently, acupuncture is licensed in 47 states and the District of Columbia, with licensure standards varying within the scope of practice of each state. Licensure for nonphysicians generally requires 3 years of accredited training and the successful completion of a standardized examination. The main accrediting organization is the Accreditation Commission for Acupuncture and Oriental Medicine. Acupuncture is included in doctor of medicine (MD) and doctor of osteopathic medicine (DO) licensure in 35 states, with 15 states requiring additional training for physicians performing acupuncture.

MIND AND BODY INTERVENTIONS

Mind and body practices and disciplines consist of physical procedures or exercises, manual therapies, or mental techniques that are administered or taught to others by a clinician, trained practitioner, or teacher. Examples include acupuncture, massage therapy, meditation, relaxation techniques, spinal manipulation, and yoga. These approaches are being used more frequently in mainstream health care facilities for both patients and health care providers. Mind and body practices such as meditation and yoga are not licensed in any state, and training in those practices is not subject to national accreditation.

Painful conditions are the most common reasons why American adults use complementary health approaches. About 40 million American adults experience severe pain in any given year, and they spend >$14 billion out-of-pocket on complementary approaches to manage such painful conditions as back pain, neck pain, and arthritis. Chronic pain management is often refractory to conventional medical approaches, and standard pharmacologic approaches have substantial drawbacks. Health care guidelines of the American Pain Society, the American College of Physicians, and other professional organizations

recognize the value of certain complementary approaches as alternatives or adjuncts to pharmacologic management.

The evidence base for the effectiveness of these modalities is still relatively incomplete, but a few rigorous examples where there is promise of usefulness and safety include acupuncture and tai chi for osteoarthritis of the knee pain; massage for neck pain; tai chi for fibromyalgia pain; relaxation techniques for headaches and migraine; and acupuncture, massage, yoga, and spinal manipulation for chronic back pain. In addition, new research is shedding light on the effects of meditation and acupuncture on central mechanisms of pain processing and perception and regulation of emotion and attention. Although many unanswered questions remain about these effects, findings are pointing to scientifically plausible mechanisms by which these modalities might yield benefit.

DIETARY SUPPLEMENTS

Regulation The Dietary Supplements Health and Education Act (DSHEA), passed in 1994, gives authority to the U.S. Food and Drug Administration (FDA) to regulate dietary supplements, but with expectations that differ in many respects from the regulation of drugs or food additives. Purveyors of dietary supplements cannot claim that they prevent or treat any disease. They can, however, claim that they maintain "normal structure and function" of body systems. For example, a product cannot claim to treat arthritis, but it can claim to maintain "normal joint health." Homeopathic products predate FDA drug regulations and are sold with no requirement that they be proved effective. Although homeopathic products are widely believed to be safe because they are highly dilute, one product, a nasal spray called Zicam, was withdrawn from the market when it was found to produce anosmia, probably because of a significant zinc content. In January 2017, the FDA warned consumers about homeopathic teething tablets containing belladonna that pose a serious risk to infants and children.

Regulation of advertising and marketing claims is the purview of the Federal Trade Commission (FTC). The FTC does take legal action against promoters or websites that advertise or sell dietary supplements with false or deceptive statements. Misleading marketing of homeopathic products, and indeed other complementary health products and practices, contributes to the very significant risk that individuals will use them instead of effective conventional modalities.

Inherent Toxicity Although the public may believe that "natural" equates with "safe," it is abundantly clear that natural products can be toxic. Misidentification of medicinal mushrooms has led to liver failure. Contamination of tryptophan supplements caused the eosinophilia-myalgia syndrome. Herbal products containing particular species of *Aristolochia* were associated with genitourinary malignancies and interstitial nephritis. In 2013, dietary supplements containing 1,3-dimethylamylamine (DMAA), often touted as a "natural" stimulant, led to cardiovascular problems, including heart attacks. Among the most controversial dietary supplements is *Ephedra sinica*, or ma huang, a product used in traditional Chinese medicine for short-term treatment of asthma and bronchial congestion. The scientific basis for these indications was revealed when ephedra was shown to contain the ephedrine alkaloids, especially ephedrine and pseudoephedrine. With the promulgation of the DSHEA regulations, supplements containing ephedra and herbs rich in caffeine sold widely in the U.S. marketplace because of their claims to promote weight loss and enhance athletic performance. Reports of severe and fatal adverse events associated with use of ephedra-containing products led to an evidence-based review of the data surrounding them, and in 2004, the FDA banned their sale in the United States.

Another major current concern with dietary supplements is adulteration with pharmacologic active compounds. Multi-ingredient products marketed for weight loss, body building, "sexual health," and athletic performance are of particular concern. Recent FDA recalls have involved contamination with steroids, diuretics, stimulants, and phosphodiesterase type 5 inhibitors.

This website provides an interactive natural product–drug interaction checker tool that identifies interactions between drugs and natural products, including herbals and dietary supplements. This service is available by subscription. A PDA version is available.	

Abbreviation: PDA, personal digital assistant.

Herb–Drug Interactions A number of herbal products have potential impact on the metabolism of drugs. This effect was illustrated most compellingly with the demonstration in 2000 that consumption of St. John's wort interferes with the bioavailability of the HIV protease inhibitor indinavir. Later studies showed its similar interference with metabolism of topoisomerase inhibitors such as irinotecan, with cyclosporine, and with many other drugs. The breadth of interference stems from the ability of hyperforin in St. John's wort to upregulate expression of the pregnane X receptor, a promiscuous nuclear regulatory factor that promotes the expression of many hepatic oxidative, conjugative, and efflux enzymes involved in drug and food metabolism.

Because of the large number of compounds that alter drug metabolism and the large number of agents some patients are taking, identification of all potential interactions can be a daunting task. Several useful Web resources are available as information sources **(Table 469-2)**. Clearly, attention to this problem is particularly important with drugs with a narrow therapeutic index, such as anticoagulants, antiseizure medications, antibiotics, immunosuppressants, and cancer chemotherapeutic agents.

PATIENT AND PROVIDER RESOURCES

Physicians regularly face difficult challenges in providing patients with advice and education about complementary practices. Of particular concern to all physicians are practices of uncertain safety and practices that raise inappropriate hopes. Cancer therapies, antiaging regimens, weight-loss programs, sexual function, and athletic performance are frequently targeted for excessive claims and irresponsible marketing. A number of Internet resources provide critical tools for patient education **(Table 469-3)**. Because many complementary health products and practices are used as self-care and because many patients research these approaches extensively on the Internet, directing patients to responsible websites can often be very helpful.

The scientific evidence regarding complementary therapies is fragmentary and incomplete. Nonetheless, in some areas, particularly pain management, it is increasingly possible to perform the kind of rigorous systematic reviews of complementary health approaches that are the cornerstone of evidence-based medicine. A particularly valuable resource in this respect is the Cochrane Collaboration, which has performed >300 systematic reviews of complementary health practices. Practitioners will find this a valuable source to answer patient questions. Practice guidelines, particularly for pain management, are also available from several professional organizations. Links to these resources are provided in Table 469-3.

SUMMARY

The use of complementary, alternative, and integrative health approaches reflects an active interest in improved health. An array of unproven modalities will always be used by our patients. While some of these choices need to be actively discouraged, many are in fact innocuous and can be accommodated. Some may be genuinely helpful, particularly in the management of troublesome symptoms. An important step in patient-centered care is understanding patients' beliefs and expectations and what they are doing to manage their health, including the use of complementary health approaches, and using those insights to help guide health-seeking practices in a constructive way.

470 Telomere Disease

Rodrigo T. Calado, Neal S. Young

DEFINITION

In telomere diseases (also called *telomeropathies* or *telomere spectrum disorders*), organ dysfunction is caused by loss of the ends of chromosomes, a process termed *accelerated telomere attrition*. Inadequate repair or insufficient protection of telomeres and their resulting erosion induces cell death, deficient cell proliferation, and chromosome instability; affected tissues show defective organ regeneration, fibrosis or replacement by fat, and a proclivity for cancer. A variety of regenerative disorders affecting especially the bone marrow, lungs, liver, and skin share telomere dysfunction and loss as their common molecular mechanism. It is important to note that telomeres appear to shorten with time based on cross-sectional data of average telomere length in groups of people at different ages. However, limited data exist about telomere shortening longitudinally in individual people. Despite shortening of telomeres over time, normal aging is not associated with the development of disease from short telomeres. In normal aging, sufficient stem cell number and function are maintained to sustain vital processes. Even a patient who receives a limited number of hematopoietic cells from an adult donor is capable of maintaining normal hematopoiesis for many years, at least in part related to normal telomerase function and telomere repair. When symptoms develop as a consequence of short telomeres, a disease process is at work.

DISEASE MECHANISM

Telomeres, the physical termini of linear chromosomes, are repeated hexanucleotide sequences physically associated with specific proteins. Telomeres function to protect the chromosome ends against recognition as damaged or infectious DNA by the DNA repair machinery (Fig. 470-1). During mitosis, the DNA polymerase employs an RNA oligonucleotide with a 3′ hydroxyl group to prime replication. The primer dissociates as the DNA polymerase advances along the template strand, and a gap is left at the ends of linear DNA molecules: the newly synthesized DNA strand is necessarily shorter than the original template—the "end-replication problem." Chromosome erosion is thus inevitable with mitotic cell division, but the noncoding telomeric long, repetitive structure buffers loss of genetic information. In human cells, telomeres are composed of hundreds to thousands of TTAGGG tandem repeats in the leading and CCCTAA in the lagging DNA strand. At birth, telomeres are relatively long but they inexorably shorten with chronological aging (Fig. 470-1). In an individual cell, critically short telomere length triggers the p53 pathway, usually leading to proliferative arrest, senescence, and apoptosis. Telomere loss is the molecular basis for the "Hayflick phenomenon," the limit to cell division and thus to cell proliferation in tissue culture. If a cell overrides proliferation arrest, extremely short telomeres may engage the DNA damage repair machinery, and chromosome end-to-end fusions, chromosome breaks, aneuploidy, and chromosome instability may occur. In addition to the telomere repeated sequences, a group of specialized proteins, collectively termed *shelterins*, directly bind to or indirectly associate with telomeres, assisting in the organization of the telomere tertiary structure and inhibiting activity of DNA damage response proteins (Fig. 470-1).

To escape telomere attrition, cells with high proliferative demand, including embryonic and adult stem cells, lymphocytes, and the majority of cancer cells have at least two mechanisms to preserve telomere length: recombination and the capability to synthesize telomeric repeats. GTTAGG hexanucleotides are added to the 5′ end of the leading DNA strand by telomerase, a reverse transcriptase enzyme (TERT), and TERC, its RNA template, (Fig. 470-1). The telomerase holoenzyme complex is composed of two copies of TERT, TERC and dyskerin, and associated proteins. TERC binds to TERT and serves as the RNA template for its function as a reverse transcriptase. Dyskerin, encoded by

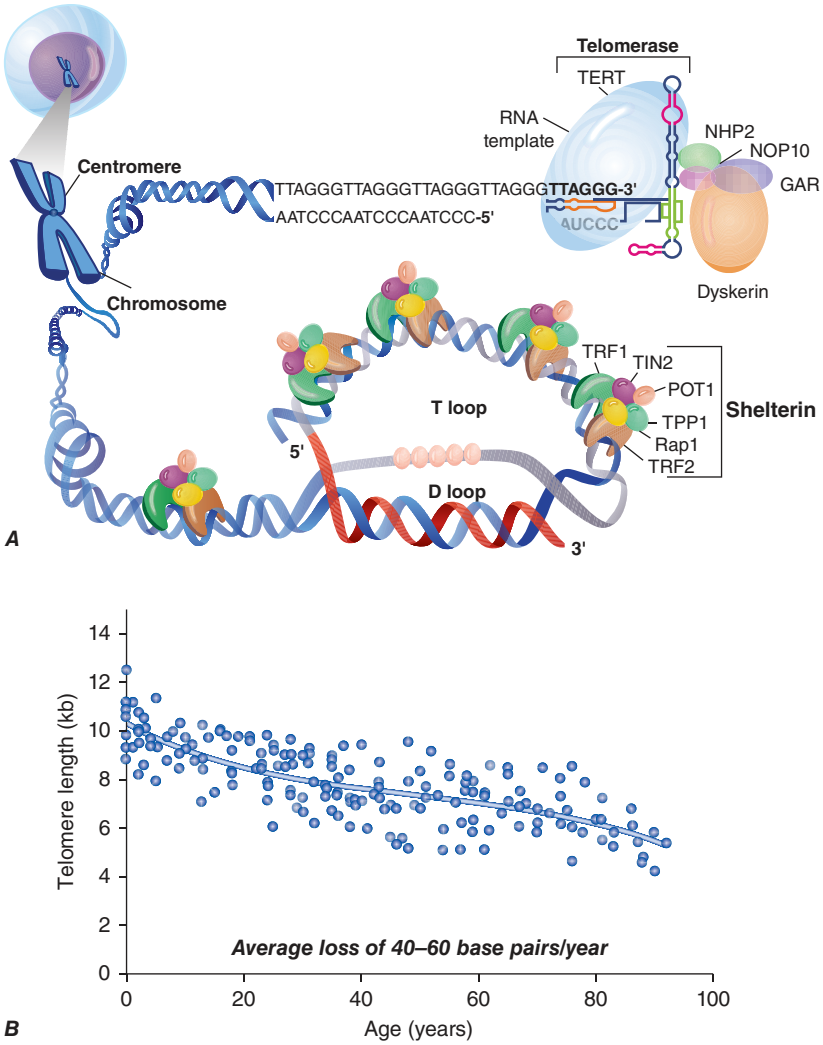

FIGURE 470-1 Telomeres and telomerase. ***A.*** Telomeres are ribonucleoprotein structures located at the termini of linear chromosomes inside the cell nucleus composed of hundreds of tandem hexameric DNA repeats. A group of proteins bind directly or indirectly to telomere sequences in order to provide protection to the structure and are collectively termed *shelterin* or *telosome* (TRF1, TRF2, TIN2, POT1, TPP1, and RAP1). As the 3' end of the leading strand forms a single-stranded overhang, it folds back and invades the telomeric double helix, forming a lariat termed *T loop*. The telomerase complex is composed of the enzyme telomerase reverse transcriptase (TERT), its RNA component (TERC), the protein dyskerin, and associated proteins (NHP2, NOP10, and GAR). This enzymatic complex elongates telomeres by adding GTTAGG hexameric repeats to the 3' end of the telomeric leading strand, using a sequence in TERC as the template. ***B.*** The average telomere length in human leukocytes varies: it is longer at birth (10–11 kilobases) and progressively shortens with aging (6–7 kilobases at age 90 years) at an average loss of 40–60 base pairs/year. However, there is significant variability in telomere length in each given age.

DKC1, stabilizes the complex, and TCAB1, encoded by the *WRAP53* gene, aids telomerase trafficking to the Cajal bodies, nuclear structures for ribonucleoprotein processing where telomerase associates with telomeres for elongation. Telomerase expression is tightly regulated. MYC and sex hormones stimulate *TERT* transcription, whereas in mature cells the *TERT* gene is heavily repressed. In addition, shelterin proteins can also regulate telomerase function and processivity, modulating its catalytic activity on telomeres. Other proteins also are important for telomere length maintenance. RTEL1, an essential DNA helicase, dismantles t-loops and resolves g-quadruplexes, ensuring adequate telomere elongation.

Pathologic accelerated telomere attrition has a genetic origin. Germ-line loss-of-function mutations in genes involved in telomere maintenance and function impair telomere length repair, thus increasing the rate of telomere erosion in highly proliferative cells. Telomeres reach critically short lengths faster than with normal aging; the consequences are limited cell proliferation and impaired tissue regeneration. Some organs appear to be particularly susceptible to telomere erosion. Billions of blood cells are produced daily (Chap. 92), and telomere attrition curtails cell proliferation, producing a hypocellular marrow and often low blood counts. The liver also is an organ with high proliferative capacity, and telomere dysfunction impairs hepatic regeneration after injury, with a variety of pathologic consequences. The lung alveolar epithelium is in contact with exogenous toxins that stimulate regeneration, and telomere loss may hamper these physiologic responses. However, it remains unclear why other regenerative tissues, like the intestine, are relatively unaffected by telomere dysfunction, or the mechanism by which telomere loss provokes a fibrotic response in the lungs (pulmonary fibrosis), an adipose response in the marrow (aplastic anemia), and both in the liver (hepatic steatosis and cirrhosis).

When telomeres are critically short, the DNA damage response machinery may be recruited, mistaking telomeres for damaged or infectious DNA and forcing inappropriate repair. Activation of this pathway may cause chromosome instability due to end-to-end fusion of chromosomes or translocations; these alterations generate unstable, potentially malignant clones. That telomere dysfunction increases the risk of cancer development has been demonstrated in murine models of telomerase deficiency, and patients with telomere diseases are especially prone to develop acute myeloid leukemia and head and neck squamous cell carcinomas.

GENETICS

The pattern of inheritance is variable: X-linked, autosomal recessive, and autosomal dominant. At least 13 genes are implicated in the etiology of telomeropathies, which may be grouped in three categories (Table 470-1).

TABLE 470-1 Genetic Variants in 13 Genes Involved in Telomere Maintenance, Inheritance Pattern, and Phenotype

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; X-L, X-linked.

CLINICAL MANIFESTATIONS

Presentation of telomere disease in the clinic is highly variable—in the tissues affected, in the severity of organ dysfunction, and in patterns of disease within families and between families with similar mutations. In a same family, one individual may be severely affected while close relatives carrying the same mutation are asymptomatic and have normal laboratory results. Asymptomatic carriers, however, may display subclinical organ dysfunction, which may be detected by directed or specialized testing (reduced forced vital capacity on pulmonary function test, hypocellular bone marrow at biopsy, hepatic steatosis on ultrasound). In addition, relatives sharing the same mutation and short telomeres may have different organs affected: for instance, while one individual may have aplastic anemia, another within the pedigree may suffer from pulmonary fibrosis. Environmental factors (smoking, alcohol consumption, viral infection) appear to cooperate with organ damage in these patients and contribute to disease heterogeneity among individuals.

Disease anticipation, in which clinical phenotype manifests at an earlier age in successive generations, is observed in some families with telomeropathies, due to the inheritance of short telomeres in sperm and oocytes.

The diagnosis usually is suggested by personal and family history and can be confirmed by simple measurement of leukocyte telomeres and next-generation sequencing of the most prominent genes encoding for telomere repair enzyme complex and shelterin components.

Dyskeratosis Congenita Dyskeratosis congenita is the classic telomere disease, a mainly pediatric syndrome diagnosed in the first two decades of life. Affected children have at least two features of the mucocutaneous triad of ungual dystrophy, reticular skin pigmentation, and oral leukoplakia (Fig. 470-2). In severe cases, affected newborns have cerebellar hypoplasia (Hoyeraal-Hreidarsson syndrome) or exudative retinopathy (Revesz syndrome) (Fig. 470-3). Telomeres are usually very short, below the first percentile expected for age (Fig. 470-4). Most patients with dyskeratosis congenita develop bone marrow failure, often requiring transfusions and bone marrow transplant. Pulmonary fibrosis appears in as many as 20% of cases and liver disease in 10%, not infrequently after bone marrow transplant. Other tissues and organs also may be affected (Fig. 470-3). The genetic defects most commonly observed in dyskeratosis congenita patients are in *DKC1*, *TINF2*, *TERT*, and *TERC* genes (Table 470-1).

Bone Marrow Failure Aplastic anemia (Chap. 98) is the most common major clinical manifestation of dyskeratosis congenita. However, young or older patients carrying a telomere defect, without typical physical stigmata of dyskeratosis, also may also develop marrow failure. Mutations are monoallelic (one mutated allele and one wild-type allele), and *TERT*, *TERC*, and *RTEL1* are the genes usually affected. Telomere loss in these cases is often less intense than in classic dyskeratosis congenita. As a result of inadequate telomerase function, the stem cell pool is limited in size and in its ability to regenerate. There is insufficient production of erythrocytes, platelets, and granulocytes with anemia, thrombocytopenia, and leukopenia of peripheral blood and relatively low marrow cellularity (Fig. 470-5). Patients can present with apparently sudden onset of severe aplastic anemia, but more common is a long history of macrocytic mild to moderate anemia and/or thrombocytopenia, with preservation of leukocyte numbers. A comprehensive personal and family history is important, querying especially for blood abnormalities, and also for lung and liver disease; early hair graying, while not specific to telomeropathies, strongly suggests telomere disease in the appropriate context.

When treated, immunosuppressive therapy is generally ineffective in these patients, and they may be more susceptible to pulmonary or hepatic complications after hematopoietic stem cell transplant.

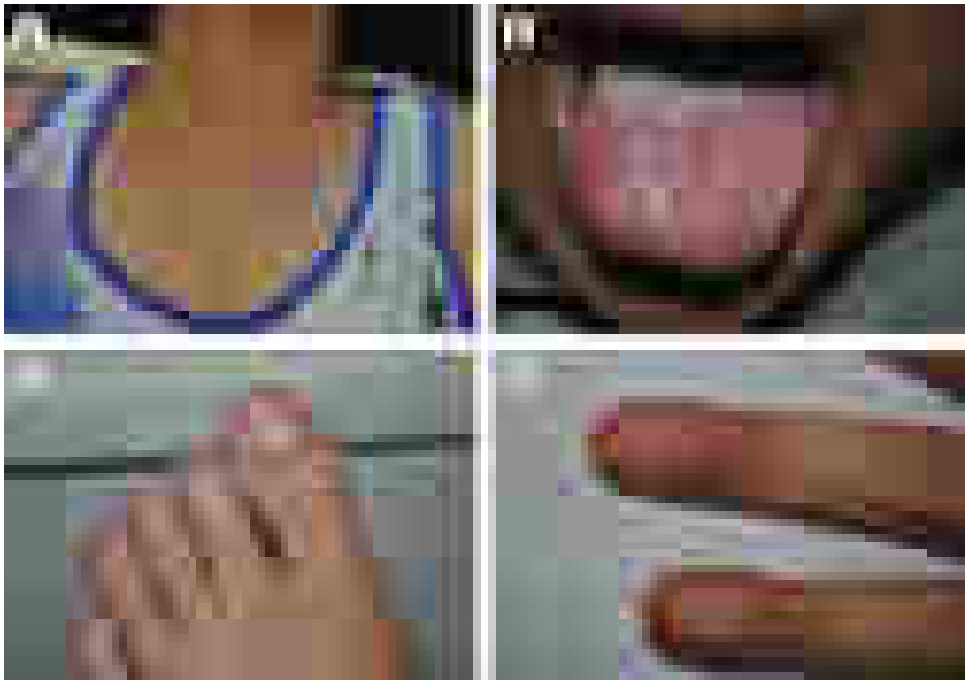

FIGURE 470-2 Skin manifestations of dyskeratosis congenita. The pediatric syndrome dyskeratosis congenita characterizes by the mucocutaneous triad of ***(A)*** reticular skin pigmentation, ***(B)*** oral leukoplakia, and ***(C, D)*** nail dystrophy.

FIGURE 470-3 Clinical consequences of telomere diseases. Telomere dysfunction affects a variety of organs: cerebellum, eyes, lungs, liver, skin, gastrointestinal tract, and the bone marrow.

Myeloid Neoplasms Some patients diagnosed with myelodysplastic syndrome (Chap. 98) or acute myeloid leukemia (Chap. 100) have a family history of bone marrow failure or of other myeloid neoplasms. One of the genetic causes for myeloid neoplasia predisposition is a telomere defect, and these disorders are now classified together by the World Health Organization as "myeloid neoplasms associated with telomere biology disorders." Telomere length measurement may be confounded by the presence of circulating immature cells, which may have very short telomeres, precluding appropriate test interpretation.

Pulmonary Fibrosis Pulmonary fibrosis appears in about 20% of children with dyskeratosis congenita, and approximately 10–15% of patients with idiopathic pulmonary fibrosis (Chap. 287) or familial pulmonary fibrosis have an etiologic telomerase gene mutation. Most pulmonary fibrosis patients, regardless of mutation status, have short telomeres for their age but not as short as in dyskeratosis congenita.

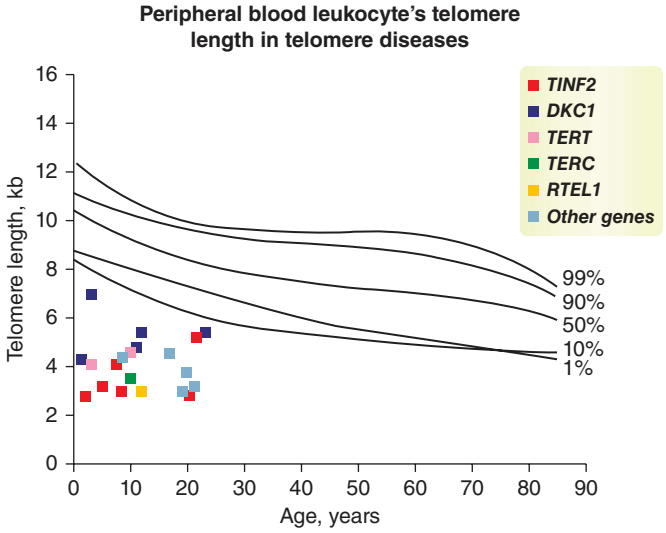

FIGURE 470-4 Telomere length measurement in dyskeratosis congenita. Telomeres shorten with aging, and solid curves represent the percentiles for age in healthy subjects. Telomeres are considered "short" when below the tenth percentile and very short when below the first percentile. In patients with dyskeratosis congenita, telomeres are usually below the first percentile, regardless of the gene lesion.

How telomere erosion causes pulmonary fibrosis is unknown, but it may prevent adequate proliferation and regeneration of pneumocytes type II. Idiopathic pulmonary fibrosis due to a telomere disease usually manifests after the fourth decade of life, with a restrictive pattern on pulmonary function testing associated with decreased diffusion capacity for carbon monoxide (DLCO) and diffuse interstitial lesion on high-resolution CT scan (Fig. 470-5). Histopathology of biopsied lung most commonly shows usual interstitial pneumonia. The pulmonary clinical presentation of patients with telomere disease is indistinguishable from idiopathic pulmonary fibrosis, except that those with an underlying telomere defect may have cryptic hepatic cirrhosis, macrocytosis, cytopenias, or a family history of lung, liver, or bone marrow disease. Pulmonary arteriovenous malformation leading to right-to-left shunting is observed in patients with pulmonary fibrosis due to telomere disease. Patients with idiopathic pulmonary fibrosis or familial pulmonary fibrosis should have their leukocyte telomere length measured and, if telomeres are short, undergo screening for mutations in telomere-associated genes and telomeres; however, telomere length may be normal in some cases despite the presence of pathogenic mutations. *TERT*, *TERC*, *RTEL1*, and *PARN* are the most commonly mutated genes.

Liver Disease Genetic telomere defects may cause hepatic cirrhosis (Chap. 337), nodular regenerative hyperplasia of the liver, nonalcoholic fatty liver disease (Chap. 336), and hepatocellular carcinoma (Chap. 78), and hepatocytes of most patients with cirrhosis have very short telomeres. Eroded telomeres limit hepatocyte proliferation, especially upon chronic injury. Additionally, hepatocytes with short telomeres display abnormal metabolic pattern and defective mitochondrial function. Abnormal liver pathology may be uncovered incidentally during the evaluation of telomeropathy patients with aplastic anemia or pulmonary fibrosis, but cirrhosis also may be the sole or most prominent clinical presentation of a telomere defect. A minority of individuals with cirrhosis associated with virus B or C infection or alcohol-associated liver disease may carry a telomere-associated gene mutation. Liver histopathology is variable, but cirrhosis is usually associated with inflammation and inflammatory cells (Fig. 470-5), increased iron deposit, positivity for CD34 in sinusoid endothelial cells, and widening of hepatocyte plates. Defective telomere maintenance may increase susceptibility of the liver to environmental challenges, such as viruses and toxins, increasing the risk for developing severe hepatic disease in mutation carriers.

TELOMERE LENGTH MEASUREMENT

Length of telomeres can be accurately measured in peripheral blood leukocytes by commercial laboratories. Of several methods available, flow-FISH and quantitative real-time polymerase chain reaction (qPCR) are the most widely utilized. Both methods have advantages and limitations and require high-quality samples, usually fresh or freshly processed, as cell death and DNA degradation impact the accuracy of testing. Results are usually expressed as leukocyte telomere length in kilobases. However, the interpretation of length must account for patient age, due to physiologic telomere loss. A normal range for telomeres is available for each year of age, longest at birth and shortening at 40–60 base pairs per year (Fig. 470-1). For each age bracket, the percentile curves are calculated and a given patient's test result is interpreted in the context of normal age variation: telomeres below the tenth percentiles for age are defined as "short" and telomeres below the first percentile are considered "very short" (Fig. 470-4).

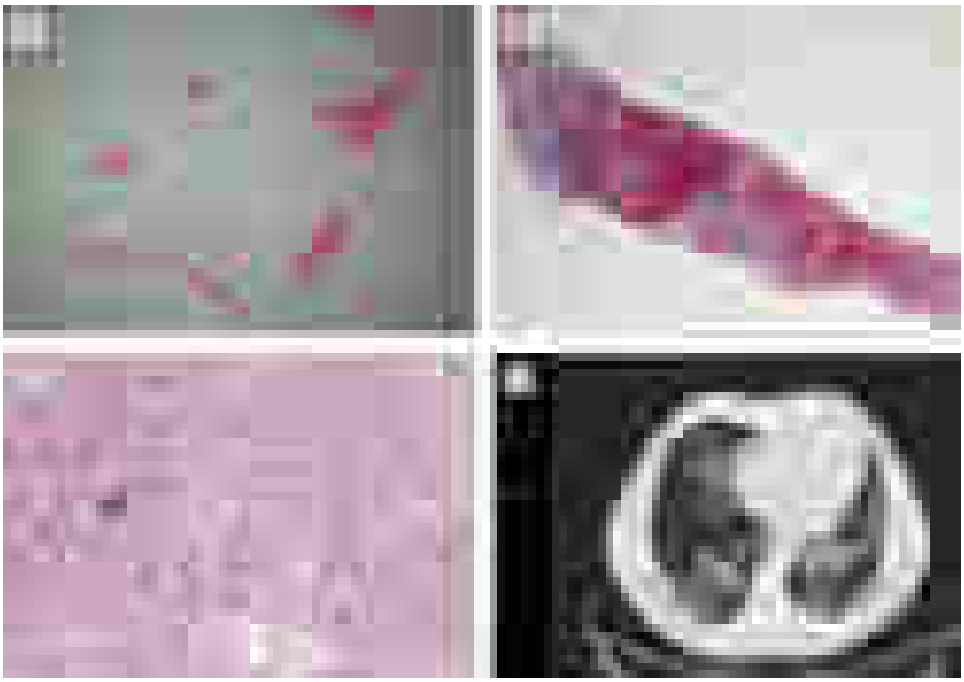

FIGURE 470-5 Pathologic manifestations of telomere diseases. ***A.*** In the bone marrow, telomere erosion predisposes to aplastic anemia, characterized by an empty hematopoietic marrow replaced by fat (hematoxylin and eosin). ***B.*** In the liver, telomere attrition predisposes to cirrhosis (hematoxylin and eosin). ***C.*** Telomere shortening may also result in nodular regenerative hyperplasia of the liver (reticulin stain). ***D.*** In the lungs, telomere dysfunction predisposes to pulmonary fibrosis mainly in the subpleural regions, which may be detected by high-resolution CT scan.

Telomeres may also be short in groups of patients with some chronic conditions, such as cardiovascular disease or diabetes. However, in these settings telomere erosion is not assumed to be etiologic, but rather a consequence of chronic inflammation; telomere testing is not known to have clinical utility and is not recommended. Likewise, telomere length tests have no known clinical utility in the assessment of aging and longevity or as a basis for therapeutic interventions absent a diagnosis of telomere disease.

Flow-FISH uses a fluorescent-labeled nucleotide probe specific for telomere repeats in order to estimate telomere content in an individual cell by flow cytometry. It has the advantage of determining telomere length in individual cells and in leukocyte subpopulations (neutrophils, lymphocytes, monocytes); lymphocyte telomere shortening is more specific for telomere diseases than in other cells. However, flow-FISH requires intact cells for analysis, not always available, and neutrophils are susceptible to damage during processing, freezing, and thawing.

Quantitative PCR (qPCR) utilizes telomere-binding modified primers to measure telomere content in comparison to a housekeeping gene in the whole leukocyte population and thus does not require intact cells. qPCR provides an estimate of the average telomere length of a given sample without determining telomere length in individual cells. Good DNA quality is essential for adequate qPCR testing and automation or semi-automation required for clinical purposes, as variability in conditions among batches may result in inter-assay variation.

GENETIC TESTING

When a patient with a suspected telomeropathy has short or very short telomeres, genetic screening for mutations in genes involved in telomere maintenance and biology is warranted (Table 470-1). Genetic testing should be restricted to patients with suspected telomere disorders. Sanger sequencing has been used for screening purposes but has been replaced by next-generation sequencing, and for telomerase complex and shelterin genes commercial panels are available. Mutations may be bi-allelic (especially in dyskeratosis congenita), but in most cases of aplastic anemia, myelodysplastic syndrome, acute myeloid leukemia, idiopathic pulmonary fibrosis, and hepatic cirrhosis, only one gene is mutated. Thus, it is crucial to appropriately interpret genetic screening results, as several rare singleton mutations of unknown significance have been identified in large cohorts of healthy individuals. In silico analysis, mutation location, and functional studies are utilized before declaring a mutation pathogenic.

Adequate genetic counseling is necessary after genetic screening, as the inheritance pattern may be autosomal dominant, mutation penetrance is highly variable, and phenotypes may be diverse even within a pedigree. Potential family stem cell donors must be screened before transplantation to ensure that they do not have mutations.

TREATMENT

Telomere Disease

Patients with severe aplastic anemia due to telomere disease may undergo allogeneic hematopoietic stem cell transplant when a suitable donor is available. Treatment-related mortality may be increased due to pulmonary and hepatic complications. Lung transplant for pulmonary fibrosis is feasible but often not performed due to coexisting cytopenias, especially thrombocytopenia, and other comorbidities. Similarly, there is no specific treatment for the liver in telomere disease; liver transplant has been attempted in rare cases. Telomeropathy patients should be advised to avoid toxins (metal dust, busulfan, amiodarone), ionizing radiation, cigarette smoke, and alcohol as possibly harmful.

Sex hormones may mitigate telomere attrition and even elongate telomere length. In case reports and a small research trial, danazol improved blood counts in marrow failure patients, and it may even slow progression of lung and liver disease in patients with telomeropathies.

471 The Role of Epigenetics in Disease and Treatment

Brian C. Capell, Shelley L. Berger

The term *epigenetics* was first coined by Waddington in 1942, as he sought to explain how changes in phenotype could occur throughout development independent of any changes to genotype. Appending the prefix *epi-* (Greek, meaning "over, outside of, around") to genetics aptly describes the numerous mechanisms by which gene expression and phenotypes are influenced, independent of any changes to the underlying DNA sequence. Today, epigenetics occupies one of the most exciting topics in biology and medicine, offering profound opportunities for discovery, as well as promise for the development of new therapies for disease. Interdisciplinary by nature, the field crosses virtually all areas of science and medicine: chemistry and genetics, development and differentiation, immunology, cancer, aging, and neuroscience.

The continuous introduction of ever more powerful techniques for interrogating the epigenome has led epigenetics to become one of the most innovative fields within the biomedical sciences. Given the vast expanse of the topic and limitations of space, in this chapter we provide a broad overview of the field and highlight key areas from across the landscape of biomedicine where epigenetics plays critical roles in disease, and importantly, where epigenetics-based therapies have demonstrated success in clinical medicine.

THE BIOCHEMICAL BASES OF EPIGENETICS

Fundamental to epigenetic regulation is the intricate organization of each cell's genome into chromatin **(Chap. 456)**. The fundamental unit of the packaging into chromatin is the nucleosome, consisting of 147 base pairs of DNA wrapped around an octamer of 8 histone proteins (two copies of each of the four core histone proteins: H2A, H2B, H3, and H4). The level of compaction of this chromatin structure determines the accessibility of the DNA strand to transcription factors, the DNA repair machinery, and other DNA-binding entities. Thus, compaction has a profound influence on gene expression levels and on local DNA mutation rates. Open regions of chromatin (euchromatin) tend to be transcriptionally active, whereas compacted chromatin (heterochromatin) tends to be transcriptionally repressed.

Histones include the four core histones, which are the most abundant and most frequently found throughout the genome, and variant histones of H2A, H2B, and H3. The structure of core and variant histones include amino- and carboxyl-terminal "tails," which are extended and unstructured, and highly conserved globular domains. The x-ray crystal structure of the nucleosome particle has illuminated the dynamic alterations of chromatin by an astounding range of regulatory mechanisms, summarized below.

The three main processes that regulate chromatin compaction, and thus access to the DNA template, include direct methylation modifications of the DNA strand itself, post-translational modifications of histones, and remodeling of nucleosomes to alter their location and composition with variant histones **(Fig. 471-1)**. The major modification of DNA is cytosine methylation of CpG dinucleotides (5-mC), associated with gene repression and catalyzed by the DNMT1, DNMT3A, and DNMT3B enzymes. DNMT3A and 3B catalyze the addition of methyl groups on unmethylated DNA de novo at CpG dinucleotides that are typically located throughout transcribed genes and in intergenic regions, but lacking at promoters, while DNMT1 is critical for the maintenance of the methylation state after DNA replication and after transcription during the S phase of the cell cycle. To further alter and reverse methylation, the TET enzymes (TET1–3) progressively oxidize 5-methylcytosine (5-mC) to 5-hydroxymethylcytosine (5-hmC), to 5-formylcytosine (5-fC) and 5-carboxylcytosine (5-caC), which are unable to be recognized by DNMT1 but can be removed by additional enzymes. Hence, these are mechanisms to passively lose 5-mC following DNA replication, or to actively remove 5-mC, both returning to unmethylated cytosine.

Histone post-translational modifications (hPTMs) are rich sources of diverse signaling to, and marking of, the chromatin template, including at least 60 different covalent chemical modifications on the histone N- and C-terminal tails and within the globular domains. The hPTMs are added (written) and removed (erased) by enzymes, and also serve as sequence- and PTM-specific binding surfaces for effector proteins and complexes (readers) to carry out a wide range of downstream actions including transcription, replication, and DNA repair and recombination. One key point is that the staggering numbers of writers, erasers, and readers provide unlimited potential for diagnostic and therapeutic pharmacologic discovery.

Throughout this chapter, we focus on histone methylation and acetylation, the most abundant and the most well-studied hPTMs (Fig. 471-1), although several others, such as serine/threonine/tyrosine phosphorylation, lysine ubiquitination, lysine SUMOylation, and lysine ADP-ribosylation also play important roles in epigenetic regulation. For instance, histone phosphorylation targets histone H2A at Ser139 (γH2A.X), which marks DNA double-strand breaks immediately following damage and is critical for the recruitment of the DNA repair machinery. Histone mono-ubiquitination functions similarly to other hPTMs, in signaling and marking the chromatin template, in particular serving to mark the initiation region or elongation of transcribed genes for future rounds of transcription, whereas histone SUMOylation plays a role in transcriptional repression. Poly-ubiquitination serves to tag proteins for degradation by the proteasome, and dysfunction in this system may play a role in the pathogenesis of neurodegenerative diseases such as Alzheimer's, Parkinson's, and Huntington's disease. ADP-ribosylation involves a class of enzymes, the poly-ADP-ribose polymerases (PARPs), which transfer ADP-ribose units from NAD+ to a variety of nuclear proteins. This PARylation alters the chromatin environment through the recruitment and modification of chromatin-associated proteins. In general, future studies of the wealth of types and functions of hPTMs will enhance our understanding of these chromatin-based mechanisms and processes and will illuminate new opportunities and targets for therapies.

In contrast, there is extensive understanding of histone lysine acetyltransferases (KATs) and methyltransferases (KMTs). KATs, previously known as HATs, were among the first identified histone modification enzymes. They attach acetyl groups on the lysine residues of histone tails and other proteins, resulting in both a novel side chain (acetyl-lysine) and an increase in negative charge (from positive charged lysine to neutral acetyl-lysine). This alteration results in loosening of chromatin structure to become more permissive to the binding of transcription factors, and it also creates a novel binding surface for the association of reader proteins. Acetylation on core histones, such as lysine 9 on histone H3 (H3K9ac) or lysine 27 (H3K27ac), is typically associated with transcriptional activation. Acetylation is very dynamic and can be rapidly removed by histone deacetylases (HDACs), of which there are multiple classes, including HDACs and sirtuins (NAD-dependent deacetylases), which return the lysine to unmodified ground state.

Methylation of histone tails by KMTs provides more nuanced regulation, in that particular methylated lysines are associated with transcriptional activation (e.g., H3K4me3, H3K36me3, H3K79me3), transcriptional repression (e.g., H3K27me3), or DNA repeat and

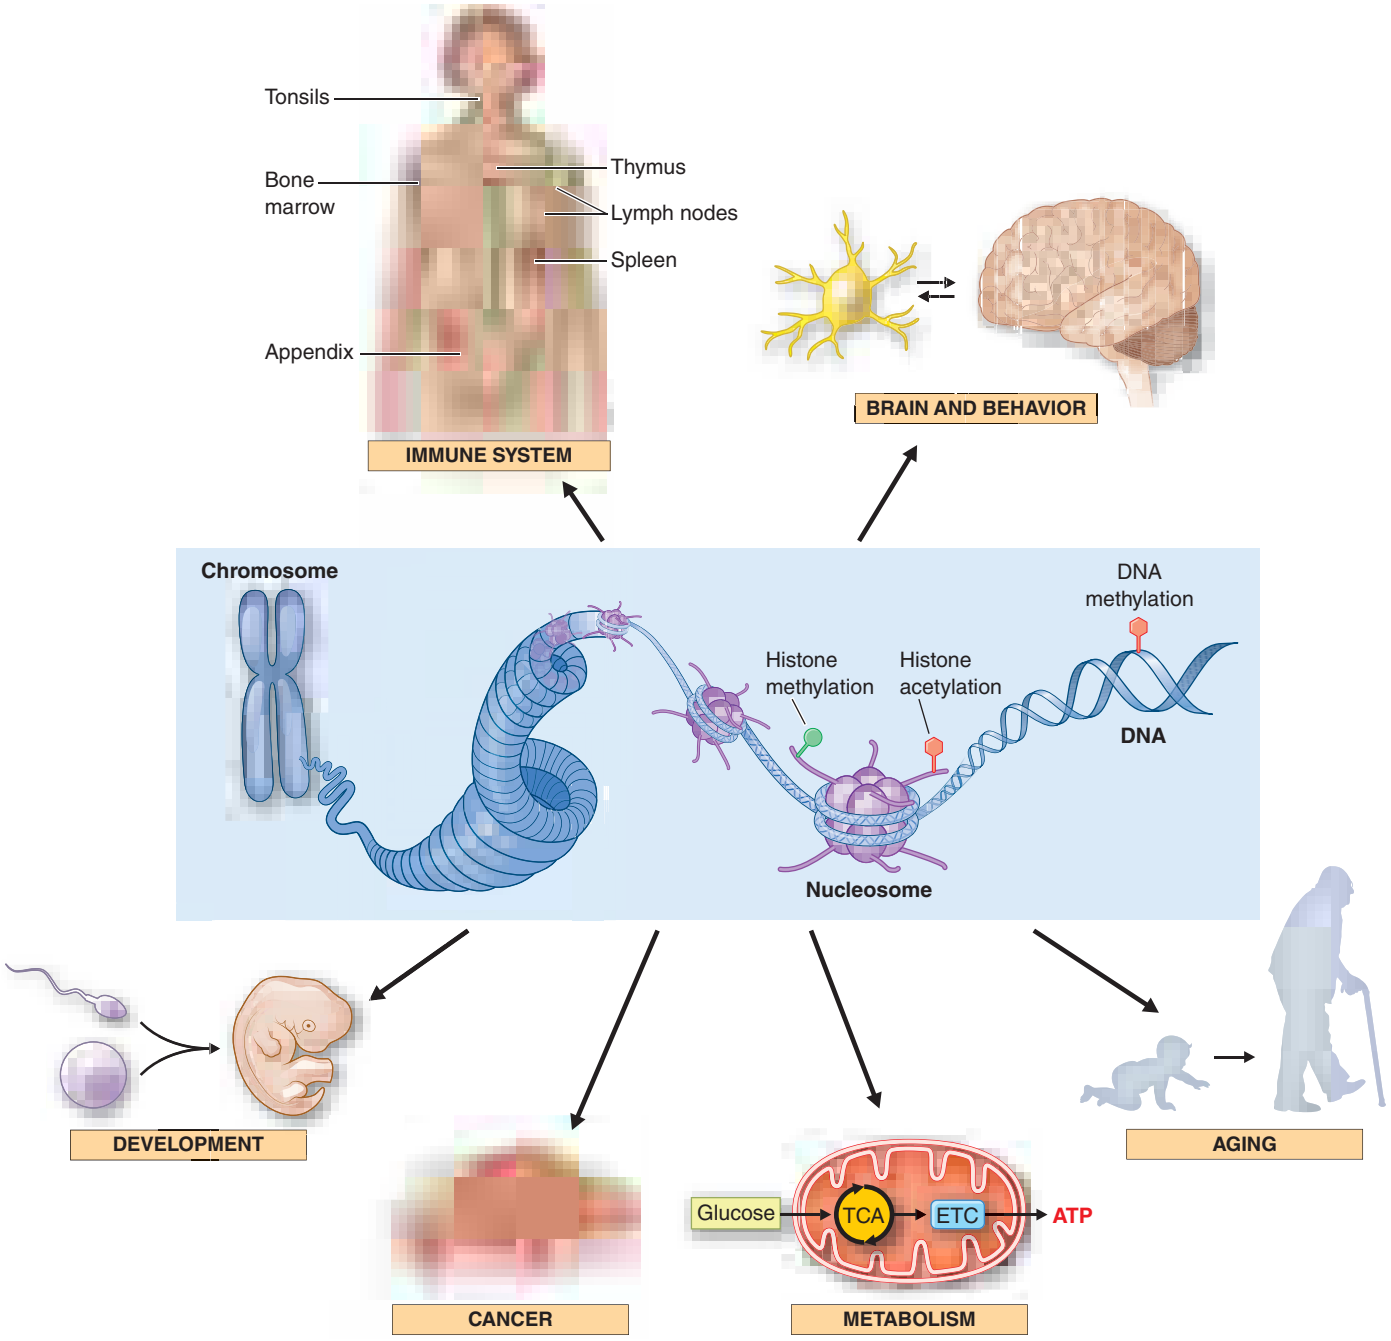

FIGURE 471-1 Epigenetic pathways influence multiple physiologic and disease pathways. As depicted in the center of the illustration, epigenetics refers to the chemical modifications of DNA and histones, which influence chromatin structure, gene expression, and susceptibility to mutations. These molecular pathways, in turn, play important roles in development, cancer, metabolism, aging, neural function, and behavior, and in the immune system.

centromeric silencing (e.g., H3K9me3). The output is strictly determined by effector protein binding, as methylation of lysine does not alter side chain electrostatic charge. Lysine methylation is a more stable chemical modification than is acetylation, and, while demethylases are identified for some of the specific methylated sites (H3K4, H3K9, H3K36, H3K27), it is provocative that H3K79 and H4K20 demethylases have not yet been discovered.

Frequently coordinating with histone modification enzymes are nucleosome remodeling enzymes, which use the energy derived from the hydrolysis of ATP to reposition and remove nucleosomes along the DNA template, and to exchange core histones and variant histones (including variants that are located at the transcriptional initiation sites [H2AZ] and over the transcribed genes [H3.3]). These complexes activate or repress transcription. The SWI/SNF family creates nucleosome-free regions for transcriptional activation, the ISWI family evenly spaces nucleosomes to repress transcription, and the INO80 family exchanges H2A with H2AZ at transcription start sites to poise transcriptional activation. Other remodeling complexes play key roles in the DNA damage response and apoptosis, among additional genomic processes.

Because multiple enzymes redundantly write, erase, and recognize many of the hPTMs, there is great complexity and the potential for fine-tuning of gene regulation. While extensive knowledge gaps remain to fully explicate mechanisms of chromatin regulation, epigenetics has become a fully established discipline within biomedical research. In the coming years, it is likely that the basic understanding of these processes will be harnessed for further betterment of human health.

EPIGENETICS IN DEVELOPMENT AND DIFFERENTIATION

Epigenetic processes are critical to organismal development and to cellular differentiation and reprogramming of cell fate (Fig. 471-1).

Transcription factors establish the epigenomic landscape that enables and stabilizes cell type–specific gene expression while simultaneously ensuring stable repression of alternative cell fates. This results in chromatin profiles that display remarkable cell-type specificity in differentiated cells, particularly at the key regulatory nodes of gene enhancers. In fact, epigenome profiling of the chromatin landscape in tumors of unknown cell origin can provide a better index of the origin tissue than does sequencing the tumor itself to catalog genetic mutations.

The cell type–specific epigenetic program is first derived from the template of embryonic stem cells, where numerous genes required for differentiation exist in a "bivalent" state, marked by both the activating histone modification, H3K4me3, and the repressive modification, H3K27me3. From this state, the genes are thought to be "poised" and ready either for activation or for repression, depending on their subsequent cell fate. Critical genes directing toward a specific cell fate will be turned on, whereas genes leading toward alternative fates will be repressed. Once differentiated, an epigenetic barrier will prevent the cells from returning to the stem cell state. For example, heterochromatin in the form of H3K9me3 can serve as a barrier to cellular reprogramming when attempting to create induced pluripotent stem cells, and inhibiting the enzymes that catalyze H3K9me3, such as SUV39H1, can enhance reprogramming efficiency.

DNA methylation contributes to the specification of cell fate and to other developmental pathways. DNA methylation alterations are involved in critical processes ranging from sex chromosome dosage compensation to coordinating expression of imprinted genes. Disruption of this latter process can lead to imprinting disorders including Prader-Willi syndrome, Angelman syndrome, and Beckwith-Wiedemann syndrome.

Beyond embryonic development, epigenetics can provide the necessary coordination and balance between adult stem cell renewal and differentiation. This epigenetic control is critical, as impaired self-renewal can lead to stem cell exhaustion and premature aging, while excessive self-renewal may promote cancer. Key epigenetic regulators tend to play conserved roles across diverse tissue types. For instance, BMI1, a component of the polycomb repressive complex 1 (PRC1), is required for stem cell proliferation and self-renewal, and its ablation leads to stem cell depletion in hematopoietic, epidermal, muscle, intestinal, and mammary stem cells. Similarly, the DNA methyltransferase DNMT1 also is required for stem cell self-renewal in hematopoietic, epidermal, and mammary stem cells. HDACs 1 and 2 possess some overlapping functions and are required for normal epidermal differentiation. Likewise, a loss of these enzymes in hematopoietic stem cells can lead to failure of differentiation and severe anemia. These factors represent repressive chromatin regulation, leading to the concept that restraining specific transcription pathways related to differentiation are crucial to maintaining undifferentiated stem cell pools.

The epigenetic regulation of the tumor suppressor p16 (*CDKN2A*) locus during differentiation provides a prime example of this finely tuned system. For example, as mentioned above, DNMT1 is necessary for self-renewal in human epidermal stem cells. Levels of DNMT1 are high in the basal undifferentiated layer of the epidermis, decreasing progressively with epidermal stratification, leading to derepression of the tumor suppressors p16 and p15, thereby promoting cell cycle arrest and full differentiation. BMI1 displays a similar phenotype in both hematopoietic and epidermal stem cells, repressing key genes that promote differentiation, such as p16 and p19ARF. Consistently, a loss of BMI1 leads to premature differentiation and defective self-renewal. In addition to the repression provided by DNMT1 and BMI1, the p16 locus is highly decorated with the repressive H3K27me3 catalyzed by EZH2 in epidermal stem cells. Then, during epidermal differentiation, H3K27me3 is removed by the KDM6B (JMJD3) histone demethylase. Loss of this control over programmed p16 expression occurs in epithelial cancers, such as squamous cell carcinoma (SCC), where EZH2 is overexpressed and KDM6B expression is lost. In the breast, progesterone can lead to increased levels of EZH2 to promote mammary epithelial cell proliferation. However, excessive EZH2 expression occurs in breast cancers, exemplifying how epigenetics can integrate environmental signals and have a profound influence on the fine balance between stem cell maintenance and overt carcinogenesis. Indeed, loss of key chromatin regulation that promotes cell differentiation, and gain of activities that promote stemness, is a recurrent theme in cancer.

Chromatin modifying enzymes also play a major role in influencing cell type specificity. High levels of EZH2 that modify H3K27me3 promote adipogenesis while simultaneously inhibiting osteogenesis. In contrast, the H3K27me3 demethylases, KDM6A (UTX) and KDM6B (JMJD3), derepress those same genes, driving stem cells toward osteogenesis. Through interactions with tissue-specific master regulators, epigenetic modifiers also shape cell type specificity. In the epidermis, p63, the p53 family member that is a master regulator of the epidermal compartment, interacts with several chromatin regulators including HDAC1 and HDAC2, SATB1, and BRG1 to orchestrate epidermal differentiation. Similarly, the gene-activating H3K4 histone methyltransferases, MLL3 (KMT2C) and MLL4 (KMT2D), are required for adipogenesis by forming a complex with the transcriptional activator ASC2 and the transcription factor PPARγ to induce adipogenic genes.

EPIGENETICS OF METABOLISM

One of the fascinating aspects of epigenetics is that it represents a mechanism for direct connection between the environment and gene expression. Numerous studies in the field of metabolism have identified a complex interplay between diet, metabolism, and the epigenome (Fig. 471-1). Seminal findings in *Drosophila* and mice have shown that changes in diet, particularly the paternal diet, and other environmental factors, can influence the metabolism of offspring, ultimately promoting obesity in later generations. Epidemiologic studies in humans have supported these results, as the nutritional status of grandparents has been correlated with phenotypic effects in grandchildren. In fact, diet can directly affect the levels and activity of chromatin modifiers. For instance, HDAC9 is elevated by high-fat diets, and inhibition of HDAC9 can be protective against the deleterious effects of high-fat diets in mice, including weight gain, decreased glucose tolerance, and increased insulin resistance.

These connections are driven by metabolites that constitute key cofactors for post-translational histone modifications such as acetylation and methylation. These include acetyl-CoA for histone acetylation and S-adenosylmethionine (SAM) for histone and DNA methylation. Levels of acetyl-CoA, in comparison to all measured metabolites, are indeed the best predictor of histone acetylation levels. Consistent with this, increased acetyl-CoA correlates with rising levels of total histone acetylation, including at the promoters of growth-associated genes. This increase in nuclear acetylation is associated with cell cycle progression and proliferation, and it can have clinically relevant downstream effects. For example, high levels of acetyl-CoA can delay stem cell differentiation and suppress autophagy. The oncogenes MYC and AKT can both hijack metabolic networks to enhance nutrient uptake by cancer cells, thus promoting acetyl-CoA production and resulting in both the initiation and progression of tumorigenesis.

Methylation is also altered by metabolism. Dietary factors are estimated to explain 30% of the variation in human serum methionine concentration, and this can alter histone methylation. For example, dietary methionine availability and intracellular production of SAM affects the levels of histone H3K4me3 associated with transcriptional activation. Furthermore, these fluctuations can have critical physiologic consequences: DNA methylation levels in rectal mucosa and colonic polyps are increased by higher levels of dietary folate, and a diet low in methyl donors reduces the formation of gastrointestinal cancers in mice predisposed to these tumors. Methionine metabolism and the availability of SAM regulates stem cell differentiation and contributes to carcinogenesis. For instance, cancers that display hypermethylation, including those with *IDH* mutations, are associated with poorly differentiated gene expression profiles. In contrast, loss of the *MTAP* gene, which is part of the 9p21 locus containing p16, and one of the most frequent events in human cancer, disrupts normal methionine metabolism. While this lowers methylation levels, interestingly, it can also sensitize cancer cells to inhibitors of the PRMT5 methyltransferase,

therefore opening a new therapeutic opportunity. These observations illustrate how connections between epigenetics and metabolism can generate unanticipated advances in medicine.

CANCER EPIGENETICS

Cancer is now understood to be a mixed genetic and epigenetic disease, as epigenetic dysregulation is pervasive in human cancers (Fig. 471-1). Beyond simple activation of oncogenes or reduced expression of tumor suppressors, epigenetic mechanisms can contribute to chemotherapy resistance and to failure of antitumor immunity. Accordingly, the development of drugs targeting epigenetic pathways is one of the most active areas of clinical and pharmaceutical development, with several compounds already approved for human use and shown to be effective in a variety of cancers. Epigenetic perturbations in cancer largely affect chromatin-regulating enzymes, which represent robust targets for development of novel small-molecule inhibitors, especially as compared with canonical oncogenic transcription factors (e.g., MYC) and tumor suppressors (e.g., p53).

Epigenetics can contribute to carcinogenesis in a variety of ways. First, on a global scale, chromatin organization is the single most influential factor in determining local mutation rate across the genome. Analysis of abundant tumor sequencing data has demonstrated that heterochromatic regions of the genome contain a higher frequency of mutations compared with more open euchromatic regions. This difference is due to the improved accessibility of the DNA repair machinery to less compact, more open regions of chromatin.

The first discovery of an epigenetic mutation was found in 1998 when the chromatin remodeler *SMARCB1* was shown to drive the formation of malignant rhabdoid tumors. Extensive sequencing of human tumors from the majority of cancer types has been performed by The Cancer Genome Atlas (TCGA) consortium, and, remarkably, 25–30% of identified cancer driver mutations occur in chromatin regulatory proteins. Similar to *SMARCB1*, numerous other chromatin modifiers (e.g., methyltransferases *MLL3* and *MLL4*, and acetyltransferases *EP300* and *CBP*) and nucleosome remodeling enzymes and associated complex components (e.g., *SMARCA4*, *SMARCA2*, *ARID1A*) are heavily mutated and inactivated in many cancers. The majority of these mutations are loss-of-function mutations, and, indeed, enzymes like MLL4 and demethylase KDM6A possess tumor-suppressive activity. In contrast, the H3K27me3 histone methyltransferase EZH2 is an oncogene, and accordingly, it is overexpressed in many advanced-stage or metastatic solid tumors such as breast cancer, prostate cancer, and melanoma. Mechanistically, EZH2 represses the p16 tumor suppressor and other cell cycle genes required for cell cycle exit via H3K27me3 deposition. Consistent with a broad growth regulatory role, EZH2 inhibitors are therapeutically successful for a number of cancers in preclinical models and are being actively studied for B cell lymphoma, melanoma, and other solid tumors.

Recently, provocative evidence has emerged for a direct tumorigenic role of histones based on the discovery of causative mutations, such as histone H3 mutations identified in pediatric high-grade gliomas. Specifically, the majority of these mutations are in the H3 variant H3.3, where lysine 27 is replaced by methionine (K27M). Similarly, over 90% of chondroblastomas replace lysine 36 with methionine (K36M) in histone H3.3. These effects appear to be dominant negative because (1) in H3.3 these are heterozygous mutations, and (2) the mutations also occur in the canonical H3, which exists in approximately 30 orthologous genes in the human genome. Thus, a minority of H3/H3.3 mutant protein leads to global defects in the associated histone modifications (K27 or K36 methylation), possibly via irreversible inhibition of the cognate enzymes by the mutant histones. These histone mutations promote resistance to apoptosis and failure of normal differentiation in a number of pediatric cancers.

Beyond mutations, genetic translocations involving chromatin modifiers also implicate chromatin pathways as direct drivers in cancer. MLL1, the H3K4 histone methyltransferase, is a frequent translocation partner occurring in adult and pediatric acute myeloid leukemia (AML), and in approximately 80% of infant acute lymphoid leukemia (ALL) cases. MLL1 can fuse with more than 70 translocation partners, and these mutant proteins prevent normal hematopoietic differentiation. Consistent with a causative role of MLL1 in these gene fusions, drugs inhibiting the catalytic activity of MLL1 are effective in preclinical models of AML.

Given the abundance of epigenetic abnormalities in cancer combined with the inherent reversibility of epigenetic changes, extensive efforts are underway to develop epigenetic drugs. The first epigenetic therapeutic involved the use of DNA methylation inhibitors (DNMTi) to reactivate tumor suppressor genes. Interestingly, the mechanism of traditional chemotherapeutics, such as azacitidine and decitabine, is to inhibit DNMT1, thereby promoting global hypomethylation; these are currently in clinical use for myelodysplastic syndrome (MDS) and AML. In a second broad mechanism, loss of acetylation occurs in many cancers, and thus HDAC inhibitors (HDACi) are under intensive development. HDACi are effective and approved for treatment in cutaneous T cell lymphoma and multiple myeloma. Bromodomain (BRD)-containing proteins bind to lysine acetylated target proteins, including histones, and rationally designed BET inhibitors (BETi) block their binding. BETi reduce the amplified expression of oncogenes such as *MYC* in hematologic cancers. Current studies are focused on optimizing combinatorial therapies of these pan-DNMTi and pan-HDAC inhibitors with conventional chemotherapies and immunotherapies, particularly given the ability of epigenetic therapeutics to promote re-expression of tumor antigens and interferon (IFN)-mediated antitumor immunity.

There are several hundred chromatin enzymes and binding proteins in the human genome, and the current focus is on the identification of more specific inhibitors. Indeed, targeted inhibitors of numerous mutated chromatin regulators have been developed, with more than 30 compounds currently in various stages of development and preclinical trials. Some notable examples showing early clinical success include EZH2 inhibitors for lymphomas, sarcomas, and melanoma, IDH inhibitors for AML and gliomas carrying mutant *IDH1* or *IDH2* genes, LSD1 inhibitors for AML and small cell lung cancer, and DOT1L and MLL1 inhibitors for leukemias with activated MLL1.

EPIGENETICS OF AGING

Like many diseases of aging, human aging itself results from the complex interplay between genes and the environment. Evidence that the epigenome may be the key link between these processes derives from observations that numerous environmental stimuli and stressors—ranging from diet and exercise to hormones and circadian rhythms—contribute to both aging and epigenetic alterations (Fig. 471-1). Thus, a lifetime of exposures progressively disrupts the chromatin landscape. These age-dependent changes in chromatin organization increase the susceptibility of the genome to mutations and also reduce transcriptional fidelity. Further, provocative findings in model systems demonstrate that stress-induced epigenetic changes can be transmitted over several generations and can even affect the lifespan of later generations. Among these global epigenetic alterations, there is dysregulation of histone modifications and a general loss of histone proteins with aging across taxa. Amazingly, experimental increases in histone levels, particularly histones H3 and H4, but not H2A or H2B, can reverse these age-related changes in mammalian cells and yeast.

Thus, the sum of current evidence suggests a model of aging via a general increase in activating epigenetic modifications along with a loss of repressive modifications. Together these changes create a state of transcriptional instability and "noise" that inhibit accurate transcription. Cells from patients with Hutchinson-Gilford progeria syndrome (HGPS), the most severe form of human premature aging, display reduced levels of both H3K9me3 and H3K27me3 repressive chromatin. In another premature aging disease, Werner syndrome, DNA damage induces global loss of H3K9me3 and H3K27me3 due to the inherent absence of the Werner syndrome ATP-dependent DNA helicase, which is critical for DNA repair. Such heterochromatin loss is not limited to premature aging conditions, as aged cells derived from healthy older humans display age-dependent loss of H3K9me3 leading to aberrant expression of normally repressed transposable elements. Activation

of these mobile elements correlates with neurodegenerative disorders and may also promote other aging-related phenotypes such as cancer. Human fibroblasts undergoing cellular senescence (exit from cell cycle due to replicative or other stress) undergo destabilization of compact heterochromatin adjacent to the nuclear periphery, in so-called lamin-associated-domains (LADs). At LADs, in addition to a reduction of repressive histone modifications as discussed above, there are broad new regions of the euchromatic histone modification H3K4me3.

In addition to age-associated alterations of histone modifications, direct manipulation of chromatin modifying enzymes that control these marks affects the balance between heterochromatic and euchromatic regions, and it alters the lifespan of model organisms. Inhibiting the H3K27me3 histone demethylase UTX (KDM6A) results in increased repressive H3K27me3 and extended lifespan in *Caenorhabditis elegans*. Consistent with this, genetic reduction of enzymes (*ash-2*, *set-2*, *wdr-5*) that add the activating H3K4me3 histone modification also extends lifespan in *C. elegans*. The consequences of these genetic manipulations nicely correspond to the observed changes in histone modifications as described above. Beyond histone modifying enzymes, dysregulation of the levels or function of chromatin remodelers can also affect lifespan in model organisms. This dysregulation occurs in humans as well, as in the nucleosome remodeling deacetylase complex (NuRD), which is reduced in HGPS fibroblasts and in aged healthy donors.

In addition to age-related changes in histone methylation, histone acetylation also contributes to aging phenotypes. Dysregulation of histone acetyltransferases (HATs) and HDACs is associated with reduced longevity across model organisms. Further, sirtuin deacetylases (class III NAD^+-dependent HDACs) promote healthspan and lifespan across species as key mediators of pro-longevity effects of caloric restriction. Indeed, loss of Sirt6 results in premature aging in mice. As discussed previously, metabolism and acetylation are intricately linked, and the sirtuins, via NAD^+ levels, and other HDACs may play key roles connecting the environment, gene expression, and physiologic output. For instance, exercise in humans reduces activity of HDACs 4 and 5, leading to increased H3K36ac in skeletal muscle, which likely promotes beneficial gene expression.

Epigenetic alterations with aging are not limited to histone modifications and extend to DNA methylation. Consistent with the histone patterns, DNA methylation data support the model described above—that is, general decompaction of the epigenome with aging. Specifically, levels of 5-methylcytosine (5-mC) are reduced in senescent humans cells, and global DNA hypomethylation occurs across the human genome with aging. Concurrent with this overall hypomethylated state, there are local regions of hypermethylation focused near CpGs at gene promoters, particularly at genes that maintain cellular differentiation and cell identity. This epigenetic disruption during aging thus leads to profound changes in transcription. For example, in HSCs, DNA hypermethylation blocks proper binding of transcription factors, resulting in dysregulation of normal gene expression with aging. Importantly, these patterns are not merely stochastic alterations in response to environmental stressors throughout aging. Indeed, the methylation status of a defined number of CpG sites is a highly accurate predictor of chronologic age in human tissues. This work reveals that DNA methylation status with aging outperforms previous standard biomarkers of aging, such as p16 expression levels and telomere length, and will be highly valuable in the near future to gauge effects of treatment aiming to ameliorate diseases of aging

EPIGENETICS OF THE BRAIN AND BEHAVIOR

Brain disorders are among the greatest clinical challenges to understand and to treat. Most neurologic and psychiatric disorders result from complex dysregulation of numerous genes and pathways. In this interplay between underlying genetic predisposition and external environmental factors, aberrant epigenetic regulation is increasingly recognized as a potentially key modulator (Fig. 471-1).

More directly, however, several progressive neurodevelopmental disorders are caused by germline mutations in chromatin regulators. Mutations in methyl CpG binding protein 2 (*MECP2*), a protein important for binding to methylated DNA and contributing to gene repression, is the major cause of Rett syndrome. MeCP2 loss leads to overactive gene transcription in neurons and impaired presynaptic excitatory functions. Similarly, Kabuki syndrome, another progressive neurodevelopmental disorder, is caused by germline mutations in either the H3K4me1 histone methyltransferase, *MLL4* (*KMT2D*), or the H3K27me3 demethylase, *UTX* (*KDM6A*). This disorder may derive from dysregulation of transcriptional enhancers, a major class of gene regulatory elements, as both MLL4 and UTX play a key role in activation of enhancers. Finally, the acetyltransferase CBP (*CREBBP*) also is important for gene enhancer function, and when mutated can lead to Rubinstein-Taybi syndrome, a cause of intellectual disability.

Beyond germline mutations, altered methylation dynamics can drive disorders of neural development and of neurodegeneration. Fragile X syndrome, characterized by learning disabilities and cognitive impairment, is caused by mutations in the *FMR1* or *FMR2* genes, or by hypermethylation of the transcriptional promoters regulating *FMR1* or *FMR2*. Similarly, Prader-Willi syndrome and Angelman syndrome, neurodevelopmental conditions caused by abnormal imprinting of the paternal or maternal chromosomal region (15q11-13), respectively, are frequently caused by aberrant DNA methylation. Further, DNA hypomethylation is implicated in some neurodegenerative conditions. For instance, in Parkinson's disease, several genes involved in pathogenesis are hypomethylated due to DNMT1 depletion, including the α-synuclein gene (*SCNA*). In Alzheimer's disease (AD), DNA hypomethylation occurs at promoters of key pathogenic genes such as amyloid precursor protein (*APP*). Indeed, APP promoter methylation is responsive to environmental factors, including aging, a major risk factor for AD. Likewise, presenilin-1 (*PSEN1*) is implicated in AD and displays altered DNA methylation in response to variations in metabolic stimuli. Studies of Huntington's disease (HD) have demonstrated DNA hypomethylation and decreased histone acetylation, in part due to altered function of the acetyl transferase CBP, leading to transcriptional dysregulation. Together these observations underscore epigenetic regulation as a crucial feature of neurodegeneration.

Additional gene regulatory proteins in the nervous system interact with and are regulated by chromatin modifiers. REST (repressor element 1–silencing transcription factor) is important in neuronal homeostasis through its ability to recruit chromatin regulatory enzymes, such as histone deacetylases and histone methyltransferases, and via its control over gene expression. REST levels increase with aging and serve a protective function in neurons against age-associated stressors and loss of cognitive function associated with AD. Similar to REST, brain-derived neurotrophic factor (BDNF), another important mediator of neural development and homeostasis, is implicated in a variety of neurologic and psychiatric disorders including depression, schizophrenia, bipolar disorder, and autism. Knockdown of BDNF in the dentate gyrus leads to depression-like behavior in mouse models, and BDNF mediates effects of antidepressant therapies. Chromatin pathways, including DNA methylation/MeCP2 and H3K27me3, play a key role in BDNF regulation as observed in brains from patients with schizophrenia.

Finally, addiction medicine is another frontier where epigenetics holds great promise to reveal connections between environmental exposure and phenotypes. Although still in its early stages in terms of mechanistic understanding, emerging evidence demonstrates disruption of epigenetic homeostasis as a consequence of addictive substances ranging from alcohol to cocaine. For example, the acetylation of regulatory elements in the *FOSB* gene by the histone acetyltransferase CBP is associated with behavioral effects of cocaine. Ethanol also induces histone acetylation and a decompacted chromatin structure.

EPIGENETIC INFLUENCES ON INFECTION, IMMUNITY, AND INFLAMMATION

Alterations in gene expression patterns are important determinants of immune-mediated disease, and in turn, epigenetics regulates immunity and inflammation (Fig. 471-1). Treatment with immune-stimulating agents such as lipopolysaccharide (LPS) and TNF-α activate expression of numerous inflammatory genes within hours, with precise gene pathways and activation kinetics determined by the cellular epigenetic

state. HATs and HDACs are critical components of this response, coordinating with pro-inflammatory transcription factors such as AP-1 and NF-κB, to activate (HATs) and to repress (HDACs). For example, corticosteroids recruit HDAC2 to promoters of NF-κB-stimulated inflammatory genes to prevent activation during asthma treatment.

Type 1 IFN responses are exceptional examples of regulatory complexity governed by epigenetic control. In an unstimulated state, the H3K9 methyltransferases G9a (*EHMT2*) and EHMT1 suppress expression of IFN and IFN-induced genes. Upon induction of IFN-stimulated genes, STAT transcription factors recruit chromatin remodeling complexes, such as BAF (*SMARCA4*), and recruit HATs including p300, CBP, and GCN5 (*KAT2A*). In turn, chromatin remodeling and acetylation recruit chromatin binding proteins including the bromodomain protein, BRD4, which promotes transcriptional elongation and full activation.

Major regulators of adaptive immunity pathways are similarly epigenetically regulated. CD4+ and CD8+ T cells undergo extensive changes in histone modification profiles during differentiation to distinct subsets of effector T cells. For example, genes associated with effector T cell functions in CD8+ memory T cells (such as *PRDM1*, *KLRG1*, *IFNG*) display enrichment of H3K4me3 and low levels of H3K27me3 compared with those genes in naïve T cells. DNA methylation also plays an important regulatory role and may contribute to disease. For example, CD4+ T cells from individuals with rheumatoid arthritis (RA), systemic scleroderma, and latent autoimmune diabetes in adults display hypermethylation of the *FOXP3* gene, which activates regulatory T cells that dampen immune responses. In addition, hypermethylation of the *CTLA4* locus occurs in regulatory T cells from RA patients, impairing their immunosuppressive abilities.

Although mechanistic studies remain limited, there are numerous examples of epigenetic-based therapies associated with extensive effects on the immune system, underscoring the potential hope for eventual treatment of immune-related conditions. For example, the DNA methylation inhibitors azacitidine and decitabine have immunosuppressive effects possibly mediated by enhanced expression of *FOXP3*, which generally suppresses immune responses. HDAC inhibitors upregulate and downregulate immune genes, and they inhibit cytokine production in macrophages from patients with RA. Further, the HDAC inhibitors vorinostat and panobinostat inhibit primary B cell responses and antibody production in vitro and in vivo. Given these broad effects, it is not surprising that the HDAC inhibitor trichostatin A (TSA) has efficacy in various model systems for treatment of RA, systemic lupus erythematosus (SLE), asthma, acute kidney injury, sepsis-induced lung and cardiac damage, and acute pancreatitis. Similarly, BET inhibitors also display broad effects. They block antigen presentation and T and B cell activation, and thus have beneficial protective effects in a variety of inflammatory settings including autoimmunity, sepsis, atherosclerosis, psoriasis, periodontitis, and arthritis. Beyond these "broad-spectrum" epigenetic inhibitors, a specific inhibitor of the H3K27me3 demethylases KDM6A and KDM6B, GSK-J4, has anti-inflammatory activity, presumably by preventing loss of H3K27me3 repression over inflammatory genes.

CONCLUSIONS

Due to the enormity and complexity of the chromatin and epigenetics fields, and their reach into all areas of biology and medicine, it is not possible to cover such a broad scope in a single chapter. Thus, here we provide a concise snapshot highlighting key areas of development in medicine. We hope to have conveyed the tremendous excitement and promise that pervades the discipline. Indeed, given the exponential growth in uncovering the interface between the epigenome and epigenetic therapies with the environment and disease, there is little doubt that the coming years will bring important additions to this field.

472 Mitochondrial DNA and Heritable Traits and Diseases

Karl L. Skorecki, Bruce H. Cohen

Mitochondria are cytoplasmic organelles whose major function is to generate ATP by the process of oxidative phosphorylation under aerobic conditions. This process is mediated by the respiratory electron transport chain (ETC) multiprotein enzyme complexes I–V and the two electron carriers, coenzyme Q_{10} (CoQ_{10}) and cytochrome c. Other cellular processes to which mitochondria make a major contribution include apoptosis (programmed cell death) and additional cell type-specific functions **(Table 472-1)**. The efficiency of the mitochondrial ETC in ATP production is a major determinant of overall body energy balance and thermogenesis. In addition, mitochondria are the predominant source of reactive oxygen species (ROS), whose rate of production also relates to the coupling of ATP production to oxygen consumption. Given the centrality of oxidative phosphorylation to the normal activities of almost all cells, it is not surprising that mitochondrial dysfunction can affect almost any organ system **(Fig. 472-1)**. Until recently, it was thought that disruption of energy production was the source of the pathophysiology in those with mitochondrial dysfunction, but recent evidence suggests that free-radical production and the redox state of the mitochondria may play a role as well. Thus, physicians in many disciplines might encounter patients with mitochondrial diseases and should be aware of their existence and characteristics.

The integrated activity of estimated 1500 gene products is required for normal mitochondrial biogenesis, function, and integrity. Aside from the 37 genes that comprise the mitochondrial DNA (mtDNA)

TABLE 472-1 Functions of Mitochondria

All Cells and Tissues
Oxidative phosphorylation
Free radical production
Calcium homeostasis
Apoptosis (programmed cell death)
Tissue- or Cell-Specific
Cholesterol metabolism
Amino and organic acid metabolism
Fatty acid beta oxidation
Sex steroid synthesis
Heme synthesis
Hepatic ammonia detoxification
Neurotransmitter metabolism

molecule, the remaining 1400+ gene products are encoded by nuclear genes (referred to as nDNA) and thus follow the rules and patterns of nuclear genomic inheritance **(Chap. 456)**. These nuclear-encoded proteins are synthesized in the cell cytoplasm and imported to their location of activity within the mitochondria through a complex biochemical process. This process includes unfolding of the nuclear-encoded protein, attachment to a chaperone protein that shuttles it through a specific channel to a specific mitochondrial location, and detachment from the chaperone followed by assembly with other mtDNA- and nDNA-encoded proteins. In addition, the mitochondria contain their own small genome consisting of numerous copies (polyploidy) per mitochondrion of a circular, double-strand mitochondrial DNA (mtDNA) molecule comprising 16,569 nucleotides. This mtDNA sequence (also known as the "mitogenome") might represent the remnants of endosymbiotic prokaryotes from which mitochondria are thought to have originated. The mtDNA sequence contains a total of 37 genes, of which 13 encode mitochondrial protein components of the ETC **(Fig. 472-2)**. The remaining 22 tRNA- and 2 rRNA-encoding genes are mitochondria-specific and dedicated to the process of translating the 13 mtDNA-encoded proteins. The mtDNA itself replicates constantly, independent of cell division, and requires its own unique polymerase, referred to as polymerase gamma (polγ), which is encoded by the nuclear protein *POLG*, disorders of which are discussed in **Chaps. 457 and 441**. However, mutations in *POLG* can disrupt the endonuclease function of polγ, resulting in somatic mutations in the mtDNA that endure with future replication. Unless this mutation occurs and repopulates in an oocyte, it is not heritable. This dual nuclear and mitochondrial genetic control of mitochondrial function results in unique and diagnostically challenging patterns of inheritance. The current chapter focuses on heritable traits and diseases related to the mtDNA component of the dual genetic control of mitochondrial function. The reader is referred to **Chaps. 456 and 441** for consideration of mitochondrial disease originating from mutations in the nuclear genome. The latter include: (1) disorders due to mutations in nuclear genes directly encoding structural components or assembly factors of the oxidative phosphorylation complexes, (2) disorders due to mutations in nuclear genes encoding proteins indirectly related to oxidative phosphorylation, (3) mtDNA depletion syndromes (MDSs) characterized by a reduction of mtDNA copy number in affected tissues without mutations or rearrangements in the mtDNA, and (4) disorders due to mutations in nuclear genes that disrupt normal mitochondrial dynamics (biosynthesis, mitophagy, fission, and fusion).

The classic physical structure of the mitochondria is that of a thread-like organelle, which under fixed conditions, such as observed with immunohistochemical stains or electron microscopy, has a submarine-shape and measures about 1 μm in length. However, in the living state, mitochondrial shape is highly variable based on the cell type, and manifests a complex and ever-changing syncytial form, with continuous appearance and disappearance of budding structures (representing mitochondrial fission) and reorganization of separate mitochondria (representing mitochondrial fusion). Although we often think of the *mitochondrial number* in an individual cell, in fact the more accurate concept in a living cell is probably mitochondrial volume.

Although the presence of mitochondria have been known for >150 years, the first knowledge of their respiratory function was proposed about 100 years ago, and the initial description of an illness linked to mitochondrial dysfunction was only made in 1962. The presence of mtDNA was noted in the 1960s and it was not until 1988 when the first mutations in the mtDNA causing human illness were described. These included the demonstration of a large-scale mtDNA deletion causing Kearn-Sayre Syndrome (KSS) and the discovery of a point mutation in *ND4*, an mtDNA-encoded complex I gene causing Leber's Hereditary Optic Neuropathy (LHON). Following these two discoveries, >400 pathogenic mtDNA mutations or deletions have been reported to cause human disease.

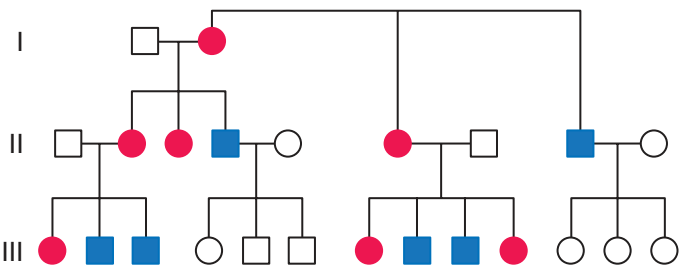

FIGURE 472-2 Maternal inheritance of mitochondrial DNA (mtDNA) disorders and heritable traits. Affected women (*filled circles*) transmit the trait to their children. Affected men (*filled squares*) do not transmit the trait to any of their offspring.

MITOCHONDRIAL DNA STRUCTURE AND FUNCTION

As a result of its circular structure and extranuclear location, the replication and transcription mechanisms of mtDNA differ from the corresponding mechanisms in the nuclear genome, whose nucleosomal packaging and structure are more complex. Specifically, mitochondria have their own transcription system, and the mtDNA itself replicates independently of cellular replication. Because each cell contains many copies of mtDNA, and because the number of mitochondria can vary during the lifetime of each cell, mtDNA copy number is not directly coordinated with the cell cycle. Thus, vast differences in mtDNA copy number are observed between different cell types and tissues and during the lifetime of a cell. Another important feature of the mtDNA replication process is a reduced stringency of proofreading and replication error correction, leading to a greater degree of sequence variation compared to the nuclear genome. Some of these sequence variants are silent polymorphisms that do not have the potential for a phenotypic or pathogenic effect, whereas others may be considered pathogenic mutations. There are some mutations that may be considered ecogenetic, as they typically remain silent, meaning they do not cause disease, unless an external event occurs. One classic example is seen in a common (1:800) mutation in the mitochondrial 12S rRNA gene, m.A1555G., which is associated with hearing loss but is rapidly exacerbated by exposure to normal dosages of an aminoglycoside.

With respect to transcription, initiation can occur on both strands and proceeds through the production of an intronless polycistronic precursor RNA, which is then processed to produce the 13 individual mRNA and 24 individual tRNA and rRNA products. The 37 mtDNA genes comprise fully 93% of the 16,569 nucleotides of the mtDNA in what is known as the *coding region*. The *control region*, which is contained in the D-loop, consists of ~1.1 kilobases (kb) of noncoding DNA, which is thought to have an important role in replication and transcription initiation.

MATERNAL INHERITANCE AND LACK OF RECOMBINATION

In contrast to homologous pair recombination that takes place in the nucleus, mtDNA molecules do not undergo recombination, such that mutational events represent the only source of mtDNA genetic diversification. Moreover, it is only the maternal DNA that is transmitted to the offspring. The fertilized oocyte degrades mtDNA carried from the sperm in a complex process involving the ubiquitin proteasome system and autophagy which takes place on the inner membrane of the oocyte. Thus, although mothers transmit their mtDNA to both their sons and daughters, only the daughters are able to transmit the inherited mtDNA to future generations. Accordingly, mtDNA sequence variation and associated phenotypic traits and diseases are inherited exclusively along maternal lines, meaning both sons and daughters have equal chances of having symptomatic disease, with the only significant exception being LHON as described below.

The phenotypic expression, including age of onset and the exact pattern of organ dysfunction, of a pathogenic mtDNA mutation may vary greatly, even within families. Because of this complex relationship between mtDNA mutations and disease expression, sometimes it is difficult to recognize the maternal pattern of inheritance at the clinical or pedigree level. However, evidence of paternal transmission can almost certainly exclude an mtDNA genetic origin of phenotypic variation or disease; conversely, a disease affecting both sexes without evidence of paternal transmission strongly suggests a heritable mtDNA disorder (Fig. 472-2).

MULTIPLE COPY NUMBER (POLYPLOIDY), HIGH MUTATION RATE, HETEROPLASMY, AND MITOTIC SEGREGATION

Each aerobic cell in the body has multiple mitochondria, often numbering many hundreds or more in cells with extensive energy production requirements. Furthermore, the number of copies of mtDNA within each mitochondrion varies from several to hundreds; this is true of both somatic as well as germ cells, including oocytes in females. In the case of somatic cells, this means that the impact of most newly acquired somatic mtDNA mutations is likely to be very small in terms of total cellular or organ system function; however, because of the many fold higher mutation rate during mtDNA replication, numerous different mutations may accumulate with aging of the organism. It has been proposed that the total cumulative burden of acquired somatic mtDNA mutations with age may result in an overall perturbation of mitochondrial function, contributing to age-related reduction in the efficiency of oxidative phosphorylation and increased production of damaging ROS. Because mtDNA (and nDNA) mutations may result in electron leak within the ETC, the ROS damage may rise above the normal baseline in some with specific mutations, resulting in increased susceptibility to somatic mtDNA damage and disease expression. The accumulation of such acquired somatic mtDNA mutations with aging may contribute to age-related diseases, such as metabolic syndrome and diabetes, cancer, and neurodegenerative and cardiovascular disease in any given individual. However, somatic mutations are not carried forward to the next generation, and the hereditary impact of mtDNA mutagenesis requires separate consideration of events in the female germline.

The multiple mtDNA copy number within each cell, including the maternal germ cells, results in the phenomenon of heteroplasmy, in contrast to much greater uniformity (homoplasy) of somatic nuclear DNA sequence. Heteroplasmy for a given mtDNA sequence variant or mutation arises as a result of the coexistence within a cell, tissue, or individual of mtDNA molecules bearing more than one version of the sequence variant **(Fig. 472-3)**. The importance of the heteroplasmy phenomena to the understanding of mtDNA-related mitochondrial diseases is critical. The coexistence of mutant and nonmutant (wild-type) mtDNA and the variation of the mutant load, which can be thought of as the percentage of mutant mtDNA molecules within a specific cell, tissue, organ or organism, contributes to the expression of a phenotype among individuals from the same maternal sibship. At the level of the oocyte, the percentage of mtDNA molecules bearing each version of the polymorphic sequence variant or mutation depends on

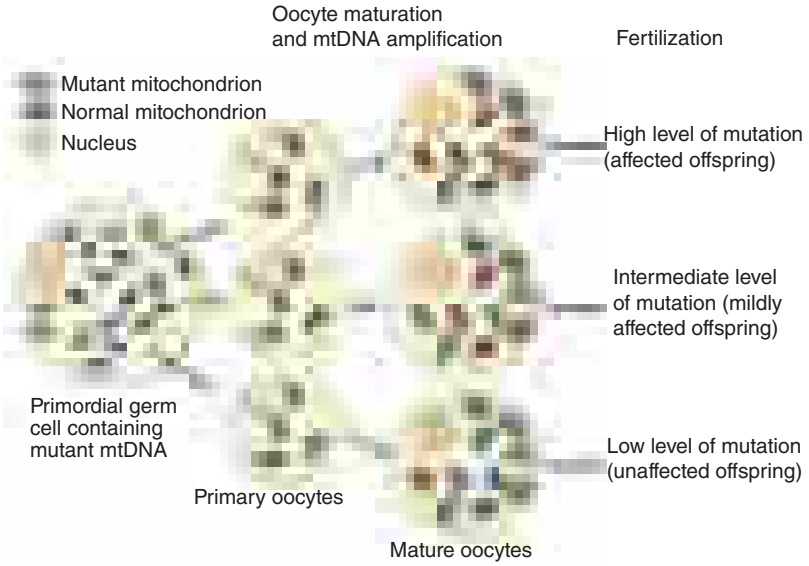

FIGURE 472-3 Heteroplasmy and the mitochondrial genetic bottleneck. During the production of primary oocytes, a selected number of mitochondrial DNA (mtDNA) molecules are transferred into each oocyte. Oocyte maturation is associated with the rapid replication of this mtDNA population. This restriction-amplification event can lead to a random shift of mtDNA mutational load between generations and is responsible for the variable levels of mutated mtDNA observed in affected offspring from mothers with pathogenic mtDNA mutations. Mitochondria that contain mutated mtDNA are shown in *red*, and those with normal mtDNA are shown in *green*. *(Reproduced with permission from R Taylor, D Turnbull: Mitochondrial DNA mutations in human disease. Nat Rev Genetics 6:389, 2005.)*

stochastic events related to partitioning of mtDNA molecules during the process of oogenesis itself. Thus, oocytes differ from each other in the degree of heteroplasmy for that sequence variant or mutation. In turn, the heteroplasmic state is carried forward to the zygote and to the organism as a whole, to varying degrees, depending on mitotic segregation of mtDNA molecules during organ system development and maintenance. For this reason, in vitro fertilization, followed by preimplantation genetic diagnosis (PGD), is not as predictive of the genetic health of the offspring in the case of mtDNA mutations as in the case of the nuclear genome. Similarly, the impact of somatic mtDNA mutations acquired during development and subsequently also shows an enormous spectrum of variability. In general, a higher mutant load will result in a more severe, and earlier phenotypic presentation. However, measuring heteroplamy in one tissue (lymphocytes from blood or urine sediment containing kidney and bladder epithelial cells for example) may not represent the percentage of mutant heteroplasmy in the tissue or organs most affected, such as the cardiac atrioventricular node or brain. Furthermore, the threshold of mutant heteroplasmy which results in clinical illness may vary depending on the specific mutation.

Mitotic segregation refers to the unequal distribution of wild-type and mutant versions of mtDNA molecules during all cell divisions that occur during prenatal development and subsequently throughout the lifetime of an individual. The phenotypic effect or disease impact will be a function not only of the inherent disruptive effect (pathogenicity) on the mtDNA-encoded gene (coding region mutations) or integrity of the mtDNA molecule (control region mutations), but also of its distribution among the multiple copies of mtDNA in the various mitochondria, cells, and tissues of the affected individual. Thus, one consequence can be the generation of a bottleneck due to the marked decline in given sets of mtDNA variants, pathogenic and nonpathogenic, consequent to such mitotic segregation. It is postulated that the main effects of this bottleneck occur between the primordial germ cell state and the primary oocyte stage of development. Heterogeneity arises from differences in the degree of heteroplasmy among oocytes of the transmitting female, together with subsequent, probably random, mitotic segregation of the pathogenic mutation during tissue and organ development, and throughout the lifetime of the individual offspring. The actual expression of disease might then depend on a threshold percentage of mitochondria whose function is disrupted by mtDNA mutations. This in turn confounds hereditary transmission patterns and hence genetic diagnosis of pathogenic heteroplasmic mutations. Generally, if the proportion of mutant mtDNA is <60%, the individual is unlikely to be affected, whereas proportions exceeding 90% cause clinical disease. One notable exception is LHON, in which these mutations are present either in 100% mutant homoplasmy, which causes the disease expression, or 100% wild-type homoplasmy. It is not understood why this specific phenotype and the several known mtDNA alleles that result in LHON behave in this manner.

HOMOPLASMIC VARIANTS AND HUMAN mtDNA PHYLOGENY

In contrast to classic mtDNA diseases, most of which begin in childhood and are the result of heteroplasmic mutations as noted above, during the course of human evolution, certain mtDNA sequence variants have drifted to a state of homoplasmy, wherein all of the mtDNA molecules in the organism contain the new sequence variant. This arises due to a "bottleneck" effect followed by genetic drift during the very process of oogenesis itself (Fig. 472-3). In other words, during certain stages of oogenesis, the mtDNA copy number becomes so substantially reduced that the particular mtDNA species bearing the novel or derived sequence variant may become the increasingly predominant, and eventually exclusive, version of the mtDNA for that particular nucleotide site. All of the offspring of a woman bearing an mtDNA sequence variant or mutation that has become homoplasmic will also be homoplasmic for that variant and will transmit the sequence variant forward in subsequent generations.

Considerations of reproductive fitness limit the evolutionary or population emergence of pathogenic homoplasmic mutations that are lethal or cause severe disease in infancy or childhood. Thus, with a number of notable exceptions (e.g., mtDNA mutations causing LHON; see below), most homoplasmic mutations are considered to be neutral markers of human evolution, which are useful and interesting in the population genetics analysis of shared maternal ancestry but which have little significance in human phenotypic variation or disease predisposition.

More importantly is the understanding that this accumulation of homoplastic mutations occurs at a genetic locus that is transmitted only through the female germline, and that lacks recombination. In turn, this enables reconstruction of the sequential topology and radiating phylogeny of mutations accumulated through the course of human evolution since the time of the most recent common mtDNA ancestor of all contemporary mtDNA sequences, some 200,000 years ago. The term *haplogroup* is usually used to define major branching points in the human mtDNA phylogeny, nested one within the other, which often demonstrate striking continental geographic ancestral partitioning. At the level of the complete mtDNA sequence, the term haplotype is usually used to describe the sum of mutations observed for a given mtDNA sequence and as compared to a reference sequence, such that all haplotypes falling within a given haplogroup share the total sum of mutations that have accumulated since the most recent common ancestor and the bifurcation point they mark. The remaining observed variants are private to each haplotype. Consequentially, human mtDNA sequence is an almost perfect molecular prototype for a nonrecombining locus, and its variation has been extensively used in phylogenetic studies. Moreover, the mtDNA mutation rate is considerably higher than the rate observed for the nuclear genome, especially in the control region, which contains the displacement, or D-loop, in turn comprising two adjacent hypervariable regions (HVR-I and HVR-II). Together with the absence of recombination, this amplifies drift to high frequencies of novel haplotypes. As a result, mtDNA haplotypes are more highly partitioned across geographically defined populations than sequence variants in other parts of the genome. Despite extensive research, it has not been well established that such haplotype-based partitioning has a significant influence on human health conditions. However, mtDNA-based phylogenetic analysis can be used both as a quality assurance tool and as a filter in distinguishing neutral mtDNA variants comprising human mtDNA phylogeny from potentially deleterious mutations.

MITOCHONDRIAL DNA DISEASE

The true prevalence of mtDNA disease is difficult to estimate because of the phenotypic heterogeneity that occurs as a function of heteroplasmy, the challenge of detecting and assessing heteroplasmy in different affected tissues, and the other unique features of mtDNA function and inheritance described above. It is estimated that at least 1 in 200 healthy humans harbors a pathogenic mtDNA mutation with the potential to causes disease, but that heteroplasmic germline pathogenic mtDNA mutations actually affect up to ~1 in 5000 individuals.

The true disease burden relating to mtDNA sequence variation will only be known when the following capabilities become available: (1) ability to distinguish a completely neutral sequence variant from a true phenotype-modifying or pathogenic mutation, (2) accurate assessment of heteroplasmy that can be determined with fidelity, and (3) a systems biology approach **(Chap. 476)** to determine the network of epistatic interactions of mtDNA sequence variations with mutations in the nuclear genome.

OVERVIEW OF CLINICAL AND PATHOLOGIC FEATURES OF HUMAN mtDNA DISEASE

Given the vital roles of mitochondria in all nucleated cells, it is not surprising that mtDNA mutations can affect numerous tissues with pleiotropic effects. More than 200 different disease-causing, mostly heteroplasmic mtDNA mutations have been described affecting ETC function. **Figure 472-4** provides a partial mtDNA map of some of the better characterized of these disorders. A number of clinical clues can increase the index of suspicion for a heteroplasmic mtDNA mutation as an etiology of a heritable trait or disease, including (1) familial clustering with absence of paternal transmission; (2) adherence to one of the

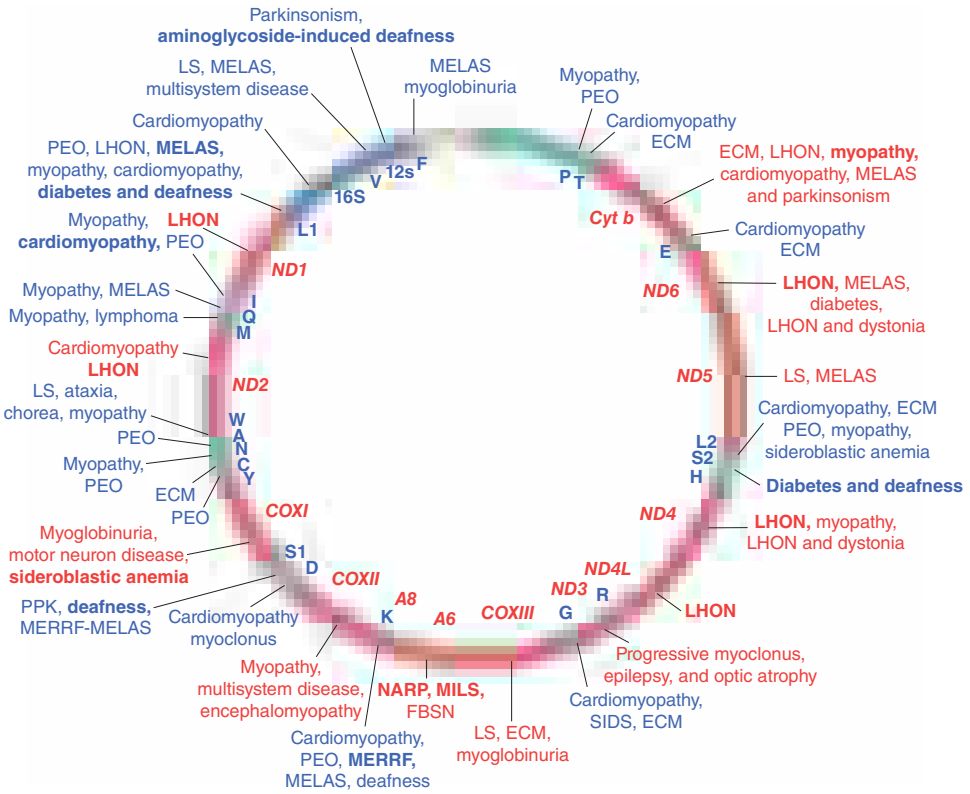

FIGURE 472-4 Mutations in the human mitochondrial genome known to cause disease. Disorders that are frequently or prominently associated with mutations in a particular gene are shown in *boldface*. Diseases due to mutations that impair mitochondrial protein synthesis are shown in *blue*. Diseases due to mutations in protein-coding genes are shown in *red*. ECM, encephalomyopathy; FBSN, familial bilateral striatal necrosis; LHON, Leber's hereditary optic neuropathy; LS, Leigh syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonic epilepsy with ragged red fibers; MILS, maternally inherited Leigh syndrome; NARP, neuropathy, ataxia, and retinitis pigmentosa; PEO, progressive external ophthalmoplegia; PPK, palmoplantar keratoderma; and SIDS, sudden infant death syndrome. *(Reproduced with permission from S DiMauro, E Schon: Mitochondrial respiratory-chain diseases. N Engl J Med 348:2656, 2003.)*

classic syndromes (see below) or paradigmatic combinations of disease phenotypes involving several organ systems that normally do not fit together within a single nuclear genomic mutation category; (3) a complex of laboratory and pathologic abnormalities that reflect disruption in cellular energetics (e.g., lactic acidosis and neurodegenerative and myodegenerative symptoms with the finding of ragged red fibers, reflecting the accumulation of abnormal mitochondria under the muscle sarcolemmal membrane); or (4) a mosaic pattern reflecting a heteroplasmic state. There are no truly sensitive and specific biomarkers of disease, and the presence of a historically quintessential finding of ragged red fibers can be seen in numerous muscle disorders, so laboratory tests must always be interpreted in the context of their limitations and should not be used to define the disease.

Heteroplasmy can sometimes be elegantly demonstrated at the tissue level using histochemical staining for enzymes in the oxidative phosphorylation pathway, with a mosaic pattern indicating heterogeneity of the genotype for the coding region for the mtDNA-encoded enzyme. Complex II, CoQ, and cytochrome c are exclusively encoded by nuclear DNA. In contrast, complexes I, III, IV, and V contain at least some subunits encoded by mtDNA. Just 3 of the 13 subunits of the ETC complex IV enzyme, cytochrome c oxidase (COX), are encoded by mtDNA, and, therefore, this enzyme has the lowest threshold for dysfunction when a threshold level of mutated mtDNA is reached. Histochemical staining for COX activity in tissues of patients affected with heteroplasmic inherited mtDNA mutations (or with the somatic accumulation of mtDNA mutations, see below) can show a mosaic pattern of reduced histochemical staining in comparison with histochemical staining for the complex II enzyme, succinate dehydrogenase (SDH) **(Fig. 472-5)**. Heteroplasmy can also be detected at the genetic level through direct Sanger-type mtDNA genotyping under special conditions, although clinically significant low levels of heteroplasmy can escape detection in genomic samples extracted from whole blood using conventional genotyping and sequencing techniques.

Next-generation sequencing (NGS) has dramatically improved the clinical genetic diagnostic evaluation of mitochondrial diseases at the level of both the nuclear genome and mtDNA. In the context of the larger nuclear genome, the ability of NGS techniques to dramatically increase the speed at which DNA can be sequenced at a fraction of the cost of conventional Sanger-type sequencing technology is particularly beneficial. Low sequencing costs and short turnaround time expedite "first-tier" screening of panels of hundreds of previously known or suspected mitochondrial disease genes or screening for the entire exome or genome in an attempt to identify novel genes and mutations affecting different patients or families. In the context of the mtDNA, NGS approaches now provide rapid and reliable detection of heteroplasmy in different affected tissues. Although Sanger sequencing allows for complete coverage of the mtDNA, it is limited by the lack of deep coverage and low sensitivity for heteroplasmy detection when levels are <50%. In contrast, NGS technology is an excellent tool for rapidly and accurately obtaining a patient's predominant mtDNA sequence and also lower frequency heteroplasmic variants and can typically detect mutant heteroplasmy <10%. Lower levels are often only clinically relevant if in the setting of a striking difference in heteroplasmy in different tissues. This capability to detect heteroplasmy at levels that assist in pointing to an mtDNA-based disease process emanates from deep coverage of the genome through multiple independent sequence reads. Accordingly, recent studies making use of NGS techniques have demonstrated sequence accuracy equivalent to Sanger-type sequencing, but also have uncovered heretofore unappreciated heteroplasmy rates ranging between 10 and 50% and detection of single-nucleotide heteroplasmy down to levels of <10%.

Clinically, the most striking overall characteristic of mitochondrial genetic disease is the phenotypic heterogeneity associated with mtDNA mutations. This extends to intrafamilial phenotypic heterogeneity for the same mtDNA pathogenic mutation and, conversely, to the overlap of phenotypic disease manifestations with distinct mutations. Thus, although fairly consistent and well-defined "classic" syndromes have been attributed to specific mutations, frequently "nonclassical" combinations of disease phenotypes ranging from isolated myopathy to extensive multisystem disease are often encountered, rendering genotype-phenotype correlation challenging. In both classical and nonclassical mtDNA disorders, there is often a clustering of some combination of abnormalities affecting the neurologic system (including optic nerve atrophy, pigment retinopathy, and sensorineural hearing loss), cardiac and skeletal muscle (including extraocular muscles), and endocrine and metabolic systems (including diabetes mellitus). Additional organ systems that may be affected include the hematopoietic, renal, hepatic, and gastrointestinal systems, although these are more frequently involved in infants and children. Disease-causing mtDNA coding region mutations can affect either one of the 13 protein encoding genes or one of the 24 protein synthetic genes. Clinical manifestations

FIGURE 472-5 Cytochrome c oxidase (COX) deficiency in mitochondrial DNA (mtDNA)-associated disease. Transverse tissue sections that have been stained for COX and succinate dehydrogenase (SDH) activities sequentially, with COX-positive cells shown in *brown* and COX-deficient cells shown in *blue*. ***A.*** Skeletal muscle from a patient with a heteroplasmic mitochondrial tRNA point mutation. The section shows a typical "mosaic" pattern of COX activity, with many muscle fibers harboring levels of mutated mtDNA that are above the crucial threshold to produce a functional enzyme complex. ***B.*** Cardiac tissue (left ventricle) from a patient with a homoplasmic tRNA mutation that causes hypertrophic cardiomyopathy, which demonstrates an absence of COX in most cells. ***C.*** A section of cerebellum from a patient with mtDNA rearrangement that highlights the presence of COX-deficient neurons. ***D, E.*** Tissues that show COX deficiency due to clonal expansion of somatic mtDNA mutations within single cells—a phenomenon that is seen in both postmitotic cells (***D***; extraocular muscles) and rapidly dividing cells (***E***; colonic crypt) in aging humans. *(Reproduced with permission from R Taylor, D Turnbull: Mitochondrial DNA mutations in human disease. Nat Rev Genetics 6:389, 2005.)*

do not readily distinguish these two categories, although lactic acidosis and specific muscle pathologic findings (e.g., ragged-red and ragged-blue fibers, described immunohistochemical staining, paracrystalline inclusions on ultrastructure) tend to be more prominent in the latter. In all cases, either defective ATP production due to disturbances in the ETC or enhanced generation of ROS has been invoked as the mediating biochemical mechanism between mtDNA mutation and disease manifestation.

mtDNA DISEASE PRESENTATIONS

The clinical presentation of adult patients with mtDNA disease can be divided into three categories: (1) clinical features suggestive of mitochondrial disease (Table 472-2), but not a well-defined classic syndrome; (2) classic mtDNA syndromes; and (3) clinical presentation confined to one organ system (e.g., isolated sensorineural deafness, cardiomyopathy, or diabetes mellitus).

Table 472-3 provides a summary of eight illustrative classic mtDNA syndromes or disorders that affect adult patients and highlights some of the most interesting features of mtDNA disease in terms of molecular pathogenesis, inheritance, and clinical presentation. The first five of these syndromes result from heritable point mutations in either protein-encoding or protein synthetic mtDNA genes; the other three result from rearrangements or deletions that usually do not involve the germline.

TABLE 472-2 Common Features of mtDNA-Associated Diseases in Adults

Neurologic: stroke, epilepsy, migraine headache, peripheral neuropathy, ataxia, dystonia, myoclonus, cranial neuropathy (optic atrophy, sensorineural deafness, dysphagia, dysphasia)
Skeletal myopathy: ophthalmoplegia, exercise intolerance, myalgia, weakness
Cardiac: conduction block, cardiomyopathy
Respiratory: hypoventilation, aspiration pneumonitis
Endocrine: diabetes mellitus, premature ovarian failure, hypothyroidism, hypoparathyroidism
Ophthalmologic: cataracts, pigment retinopathy, neurologic and myopathic (optic atrophy, ophthalmoplegia)

LHON is a common cause of maternally inherited visual failure. LHON typically presents during young adulthood with subacute painless loss of vision in one eye, with symptoms developing in the other eye 6–12 weeks after the initial onset. In some instances, cerebellar ataxia, peripheral neuropathy, and cardiac conduction defects are observed. In >95% of cases, LHON is due to one of the three homoplasmic point mutations of mtDNA that affect genes encoding different subunits of complex I of the mitochondrial ETC; however, not all individuals who inherit a primary LHON mtDNA mutation develop optic neuropathy, and males are four to five times more likely than females to be affected, indicating that additional environmental (e.g., tobacco exposure) or additional independent genetic factors are important in the etiology of the disorder. Both the nuclear and mitochondrial genomic backgrounds modify disease penetrance. Indeed, a region of the X chromosome containing a high-risk haplotype for LHON has been identified, supporting the formulation that nuclear genes act as modifiers and affording an explanation for the male prevalence of LHON. This haplotype can be used in predictive genomic testing and prenatal screening for this disease. In contrast to the other classic mtDNA disorders, it is of interest that patients with this syndrome are often homoplasmic for the disease-causing mutation. The somewhat later onset in young adulthood and modifying effect of protective background nuclear genomic haplotypes may have enabled homoplasmic pathogenic mutations to have escaped evolutionary censoring.

Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) is a multisystem disorder with a typical onset between 2 and 10 years of age. Following normal early psychomotor development, the most common initial symptoms are seizures, recurrent headaches, anorexia, and recurrent vomiting. Exercise intolerance or proximal limb weakness can be the initial manifestation, followed by generalized tonic–clonic seizures. Short stature is common. Seizures are often associated with stroke-like episodes of transient hemiparesis or cortical blindness that may produce recurrent encephalopathy with impaired consciousness. It is often not possible to determine if the encephalopathy is due to refractory seizures or should be attributed to an independent effect. The cumulative residual effects of the stroke-like episodes gradually impair motor abilities, vision, and cognition, often by adolescence or young adulthood. Sensorineural hearing loss adds to the progressive decline of these individuals. A plethora of less common symptoms have been described including myoclonus, ataxia, episodic coma, optic atrophy, cardiomyopathy, pigmentary retinopathy, ophthalmoplegia, diabetes mellitus, hirsutism, gastrointestinal dysmotility, and nephropathy. The typical age of death ranges from 10 to 35 years, but some individuals live into their sixth decade. Intercurrent infections or intestinal obstructions are often the terminal events. It is not atypical for some family members to have much less severe, or later onset illness, presumably because of a lessor mutation load, and "MELAS" is not used as a diagnosis for these restricted phenotypes. This creates somewhat of a disconnect between the genotype for MELAS (most commonly the m.3243A>G mutation), and a diverse phenotype, which includes the syndrome MELAS, as well as a syndrome of high-frequency hearing loss and diabetes with onset later in life, as well as many other phenotypes between these two extreme syndromes. Certain other mtDNA mutations can also cause such patterns

TABLE 472-3 Mitochondrial Diseases Due to mtDNA Point Mutations and Large-Scale Rearrangements

DISEASE	PHENOTYPE	MOST FREQUENT mtDNA MUTATIONS	HOMOPLASMIC (USUALLY)	MATERNAL
NARP, Leigh disease	Loss of central vision leading to blindness in young adult life	m.1778G>A, m.14484T>C, m.3460G>A	Heteroplasmic	Maternal
MELAS	*M*itochondrial encephalomyopathy, *l*actic*a*cidosis, and stroke-like episodes; may manifest only as diabetes mellitus	Point mutation in $tRNA^{leu}$	Heteroplasmic	Maternal
MERRF	*M*yoclonic epilepsy, *r*agged *r*ed *f*ibers in muscle, ataxia, increased CSF protein, sensorineural deafness, dementia	Point mutation in $tRNA^{lys}$	Heteroplasmic	Maternal
Deafness	Progressive sensorineural deafness, often induced by aminoglycoside antibiotics	m.1555A>G mutation in 12S rRNA	Homoplasmic	Maternal
	Nonsyndromic sensorineural deafness	m.7445A>G mutation in 12S rRNA	Homoplasmic	Maternal
Chronic progressive external ophthalmoplegia (PEO)	Late-onset bilateral ptosis and ophthalmoplegia, proximal muscle weakness, and exercise intolerance	Single deletions or duplications	Heteroplasmic	Mostly sporadic, somatic mutations
Pearson syndrome	Pancreatic insufficiency, pancytopenia, lactic acidosis	Large deletion	Heteroplasmic	Sporadic, somatic mutations
Kearns-Sayre syndrome (KSS)	External ophthalmoplegia, heart block, retinal pigmentation, ataxia	The 5-kb "common deletion"	Heteroplasmic	Sporadic, somatic mutations

Abbreviations: CSF, cerebrospinal fluid; NARP, neuropathy, ataxia, and retinitis pigmentosa.

of diverse phenotypic expression. Laboratory investigation commonly demonstrates elevated lactate concentrations at rest with excessive increase after moderate exercise. Brain imaging during stroke-like episodes shows areas of involvement on T2- or FLAIR sequences, with decreased signal on perfusion-weighted sequences, which typically involve the posterior cerebrum and not conforming to the distribution of major arteries. These MRI abnormalities may be temporary or evolve to subsequent atrophy **(Fig. 472-6)**. Electrocardiography (ECG) may show evidence of cardiomyopathy, preexcitation, or incomplete heart block. Electromyography and nerve conduction studies are consistent with a myopathic process, without or with coexisting axonal and sensory neuropathic findings. Muscle biopsy typically shows ragged red fibers with the modified Gomori trichrome stain or "ragged blue fibers" with the SDH histochemical stain, resulting from the hyperintense reaction. The diagnosis of MELAS is based on a combination of clinical findings and molecular genetic testing. Mutations in the mtDNA gene *MT-TL1* encoding $tRNA^{leu}$ are causative. The most common mutation, present in ~80% of individuals with typical clinical findings, is an A-to-G transition at nucleotide 3243 (m.3243A>G). Mutations can usually be detected in mtDNA from leukocytes in individuals with typical MELAS; however, the occurrence of heteroplasmy can result in varying tissue distribution of mutated mtDNA. In the absence of specific treatment, various manifestations of MELAS are treated according to standard modalities for prevention, surveillance, and treatment. Recent developments in therapy are described below.

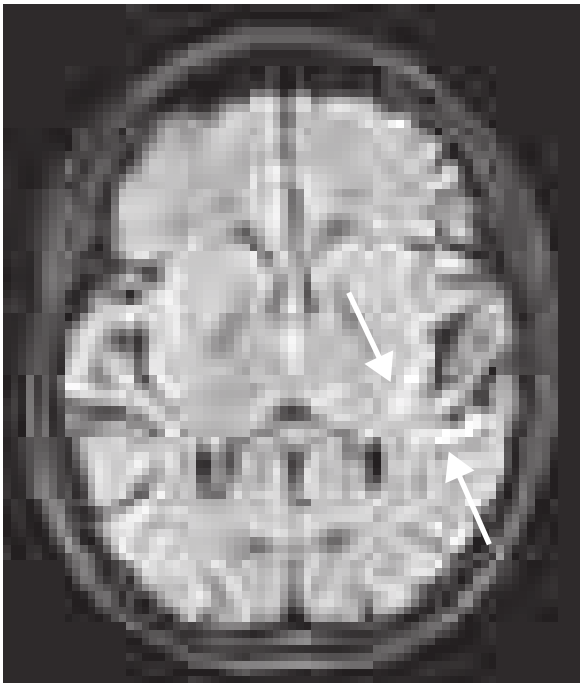

FIGURE 472-6 A 15-year-old girl with MELAS due to m.A3243G ($tRNA^{Leu(UUR)}$), 85% mutant heteroplasmy, presenting at age 5 with focal motor seizures, ataxia and short stature, with episodes of acute language and motor dysfunction and progress cognitive impairment. The FLAIR MRI shows increased signal intensity (white arrows) in the left temporal-parietal region in addition to global mild volume loss (increased extra-axial CSF spaces).

Myoclonus epilepsy with ragged red fiber (MERRF) is a multisystem disorder characterized by myoclonus, seizures, ataxia, and myopathy with ragged red fibers. Hearing loss, exercise intolerance, neuropathy, and short stature are often present. Cerebrospinal fluid (CSF) analysis reveals an elevated protein content. Almost all MERRF patients have a mutation in the mtDNA $tRNA^{lys}$ gene, and the m.8344A>G mutation in the mtDNA gene encoding the lysine amino acid tRNA is responsible for 80–90% of MERRF cases.

Neuropathy, ataxia, and retinitis pigmentosa (NARP) is characterized by moderate diffuse cerebral and cerebellar atrophy and symmetric lesions of the basal ganglia on magnetic resonance imaging (MRI: **Figs. 472-7 and 472-8**). A heteroplasmic m.8993T>G mutation in the ATPase 6 subunit gene has been identified as causative. Ragged red fibers are not observed in muscle biopsy. When >95% of mtDNA molecules are mutant, a more severe clinical, neuroradiologic, and neuropathologic picture (Leigh syndrome) emerges. Not uncommonly, an infant is diagnosed with Leigh syndrome due to the m.8993T>G mutation and not until several years later will the mother present with symptoms of NARP; a situation that highlights the concept of a higher threshold for lower levels of tissue heteroplasmy.

Point mutations in the mtDNA gene encoding the 12S rRNA (m.A1555G) result in heritable nonsyndromic hearing loss. One such mutation causes heritable ototoxic susceptibility to aminoglycoside antibiotics, which opens a pathway for a simple pharmacogenetic test in the appropriate clinical settings. This is an example of an eco-genetic disorder in that most people with this mutation do not develop any symptoms until exposed to an external agent.

KSS, sporadic progressive external ophthalmoplegia (PEO), and Pearson syndrome are three disease phenotypes caused by large-scale mtDNA rearrangements including partial deletions or partial duplication. The majority of single large-scale rearrangements of mtDNA are thought to result from clonal amplification of a single sporadic mutational event, occurring in the maternal oocyte or during early embryonic development. The typical mtDNA deletion is specifically at nucleotide 4977, accounting for most KSS and PEO of mtDNA deletion origin. Because germline involvement is rare, most cases are sporadic

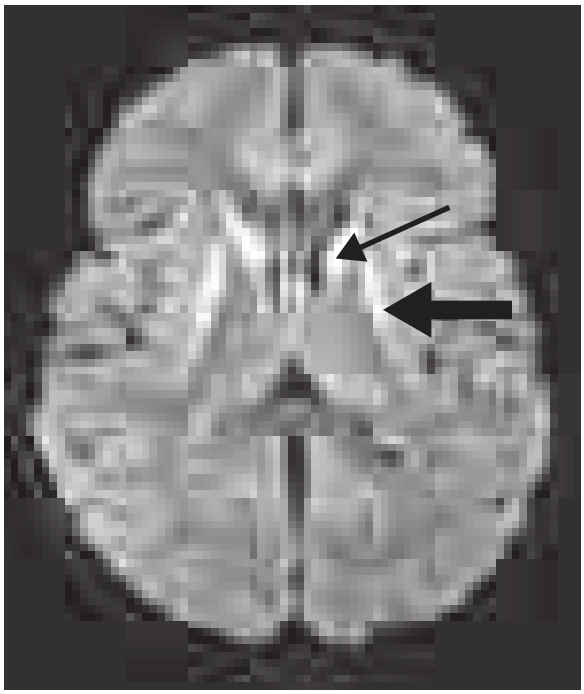

FIGURE 472-7 A 9-year-old girl with Leigh syndrome due to m.T8993G (ATPase subunit 6), 99% heteroplasmy, presenting at age 14 months with a motor delay and underwent an MRI at 24 months, at which time she had just begun to walk. She has moderate cognitive impairment, arm chorea, and distal leg dystonia. The FLAIR MRI shows symmetric bilateral increased signal in the caudate nuclei (*thin arrow*) and putamen (*thick arrow*); only left-sided lesions indicated with arrows.

rather than inherited. KSS is characterized by the triad of onset before age 20, chronic PEO, and pigmentary retinopathy. Cerebellar syndrome, heart block, increased CSF protein content, diabetes mellitus, and short stature are also part of the syndrome. Single deletions/duplication

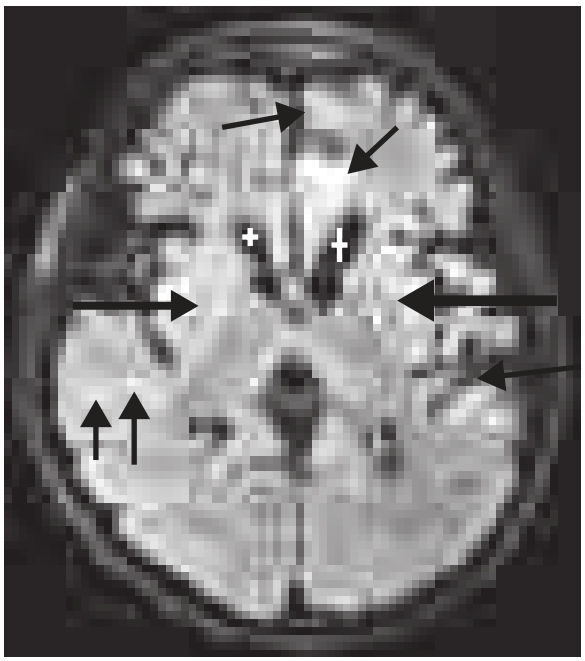

FIGURE 472-8 A 12-year-old boy with Leigh syndrome due to m.T10191C (ND3 gene, complex I), heteroplasmy percentage not determined, presenting with infantile spasms at 8 months of life. He responded well to Adrenocorticotropic Hormone (ACTH) and his MRI and development were normal until 30 months when he developed dystonia and progressive medically intractable epilepsy. The FLAIR MRI at 6 years of life shows global atrophy with large extraaxial CSF spaces, increased signal intensity in the cortex (*thin arrows*), necrotic bilaterally symmetric lesions in the putamina, and enlarged lateral ventricles due to loss of bilateral caudate nuclei volume (*stars*).

can also result in milder phenotypes such as PEO, characterized by late-onset PEO, proximal myopathy, and exercise intolerance. In both KSS and PEO, diabetes mellitus and hearing loss are frequent accompaniments. Pearson syndrome is also characterized by infantile onset of a sideroblastic anemia accompanied by lactic acidosis and failure to thrive caused in part by exocrine pancreatic insufficiency. If the child survives, the manifestations appear phenotypically similar to that of severe KSS with myopathy, PEO, encephalopathy, and cardiomyopathy. Pearson syndrome is generally caused by large-scale sporadic deletion of several mtDNA genes that differ from the common deletion seen in KSS. Typically, the deletion size is larger in Pearson syndrome than in KSS or PEO, but this is not always the case.

Two important dilemmas in classic mtDNA disease have benefited from recent important research insights. The first relates to the greater involvement of neuronal, muscular, renal, hepatic, and pancreatic manifestations in mtDNA disease in these syndromes. This observation has appropriately been mostly attributed to the high energy utilization of the involved tissues and organ systems and, hence, greater dependency on mitochondrial ETC integrity and health. However, because mutations are stochastic events, mitochondrial mutations should occur in any organ during embryogenesis and development. Recently, additional explanations have been suggested based on studies of the common m.3243A>G transition. The proportion of this mutation in peripheral blood cells was shown to decrease exponentially with age. A selective process acting at the stem cell level with a strong bias against the mutated form would have its greatest effect to reduce the mutant mtDNA only in highly proliferating cells, such as those derived from the hematopoietic system. Tissues and organs with lower cell turnover, such as those involved with mtDNA mutations, would not benefit from this effect and, thus, would be the most affected.

The other dilemma arises from the observation that only a subset of mtDNA mutations accounts for the majority of the familial mtDNA diseases. The random occurrence of mutations in the mtDNA sequence should yield a more uniform distribution of disease-causing mutations. However, recent studies using the introduction of one severe and one mild point mutation into the female germline of experimental animals demonstrated selective elimination during oogenesis of the severe mutation and selective retention of the milder mutation, with the emergence of mitochondrial disease in offspring after multiple generations. Thus, oogenesis itself can act as an "evolutionary" filter for mtDNA disease.

THE INVESTIGATION OF SUSPECTED mtDNA DISEASE

The clinical presentations of classic syndromes, groupings of disease manifestations in multiple organ systems, or unexplained isolated presentations of one of the disease features of a classic mtDNA syndrome should prompt a systematic clinical investigation as outlined in Fig. 472-9. Indeed, mitochondrial disease should be considered in the differential diagnosis of any progressive multisystem disorder. Despite the centrality of disruptive oxidative phosphorylation, an elevated blood lactate level is neither specific nor sensitive, because there are many causes of blood lactic acidosis, and many patients with mtDNA defects presenting in adulthood have normal blood lactate. An elevated CSF lactate is a more specific test for mitochondrial disease if there is central nervous system involvement. The serum creatine kinase may be elevated but is often normal, even in the presence of a proximal myopathy. Recently, testing for elevated levels of Growth Differentiating Factor 15 (GDF15) has shown a high degree of sensitivity and specificity in those with a mitochondrial myopathy, but it is not known yet if the degree of elevation for an individual patient reflects the severity of the illness or is in any way a marker of disease activity. Urinary organic and amino acids may also be abnormal, reflecting metabolic and kidney proximal tubule dysfunction. Every patient with seizures, episodes of confusion or atypical behavioral changes, or cognitive decline should have an electroencephalogram. A brain computed tomography (CT) scan may show calcified basal ganglia or bilateral hypodense regions with cortical atrophy. MRI is indicated in patients with brainstem signs or stroke-like episodes.

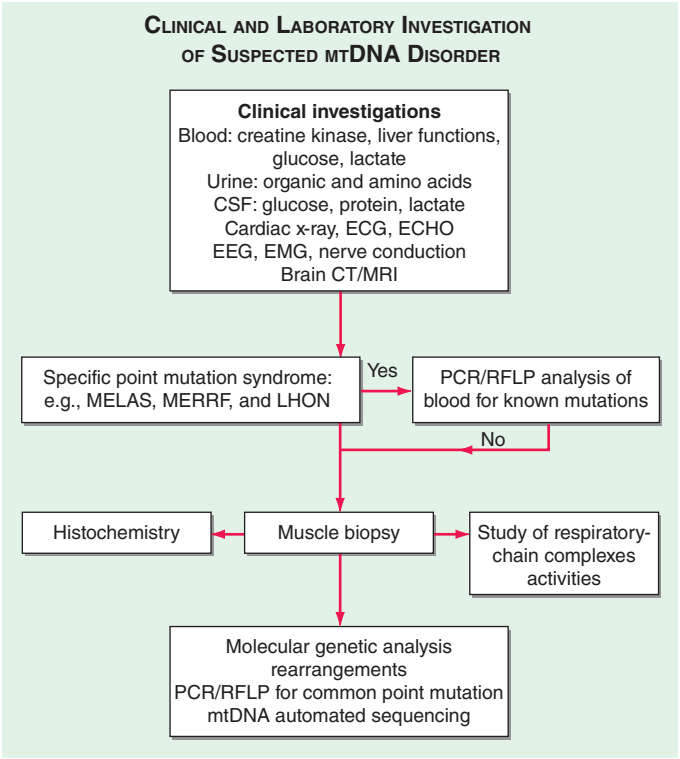

FIGURE 472-9 Clinical and laboratory investigation of a suspected mitochondrial DNA (mtDNA) disorder. CSF, cerebrospinal fluid; CT, computed tomography; ECG, electrocardiogram; ECHO, echocardiography; EEG, electroencephalogram; EMG, electromyogram; LHON, Leber's hereditary optic neuropathy; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stoke-like episodes; MERFF, myoclonic epilepsy with ragged red fibers; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; RFLP, restriction fragment length polymorphism.

For some mitochondrial diseases, it is possible to obtain an accurate diagnosis with a simple molecular genetic screen. For examples, 95% of patients with LHON harbor one of the three mtDNA point mutations (m.11778A>G, m.A3460A>G, or m.14484T>C). These patients have very high levels of mutated mtDNA in peripheral blood cells, and, therefore, it is appropriate to send a blood sample for molecular genetic analysis by polymerase chain reaction (PCR) or restriction fragment length polymorphism (RFLP). The same is true for most MERRF patients who harbor a point mutation in the lysine tRNA gene at position 8344. In contrast, patients with the m.3243A>G MELAS mutation often have low levels of mutated mtDNA in blood. If clinical suspicion is strong enough to warrant peripheral blood testing, then patients with a negative result should be repeated in a saliva sample, or investigated further by performing a skeletal muscle biopsy.

Muscle biopsy histochemical analysis had been the historical cornerstone for investigation of patients with suspected mitochondrial disease. Histochemical analysis may show subsarcolemmal accumulation of mitochondria with the appearance of ragged red fibers, especially in those with mtDNA mutations affecting the tRNA and rRNA genes. Electron microscopy might show abnormal mitochondria with paracrystalline inclusions. Muscle histochemistry may show COX-deficient fibers, which indicate mitochondrial dysfunction (Fig. 472-5). Respiratory chain complex assays may also show reduced enzyme function. If enzymatic or polarographic data are used to aid in the confirmation of diagnosis, a standard method of analysis should be employed. Either of these two abnormalities, within the exact context of established peer-reviewed criteria may confirm the presence of a mitochondrial disease, to be followed by an in-depth molecular genetic analysis. In some centers, genetic testing may immediately follow establishment of a clinical phenotype and screening biochemical labs, which may obviate the need for invasive testing.

Recent evidence has provided important insights into the importance of nuclear-mtDNA genomic cross-talk and has provided a descriptive framework for classifying and understanding disorders that emanate from perturbations in this cross-talk. Although not strictly considered as mtDNA genetic disorders, manifestations do overlap those highlighted above **(Fig. 472-10)**.

IMPACT OF HOMOPLASMIC SEQUENCE VARIATION ON HERITABLE TRAITS AND DISEASE

The relationship among the degree of heteroplasmy, tissue distribution of the mutant mtDNA, and disease phenotype simplifies inference of a clear causative relationship between heteroplasmic mutation and disease. With the exception of certain mutations (e.g., those causing most cases of LHON), drift to homoplasmy of such mutations would be precluded normally by the severity of impaired oxidative phosphorylation and the consequent reduction in reproductive fitness. Therefore, sequence variants that have reached homoplasmy should be neutral in terms of human evolution and, hence, useful only for tracing human evolution, demography, and migration, as described above. One important exception is in the case of one or more of the homoplasmic population-level variants, which designate the mtDNA haplogroup J, and the interaction with the mtDNA mutations causing LHON. Reduced disease predilection suggests that one or more of the ancient sequence variants designating mtDNA haplogroup J appear to attenuate predisposition to degenerative disease, in the face of other risk factors. Whether or not additional epistatic interactions between population-level mtDNA haplotypes and common health conditions will be found remains to be determined. If such influences do exist, then they are more likely to be relevant to health conditions in the post-reproductive age groups, wherein evolutionary filters would not have had the opportunity to censor deleterious effects and interactions and wherein the effects of oxidative stress may play a role. Although much has been written about the possible associations of population-level

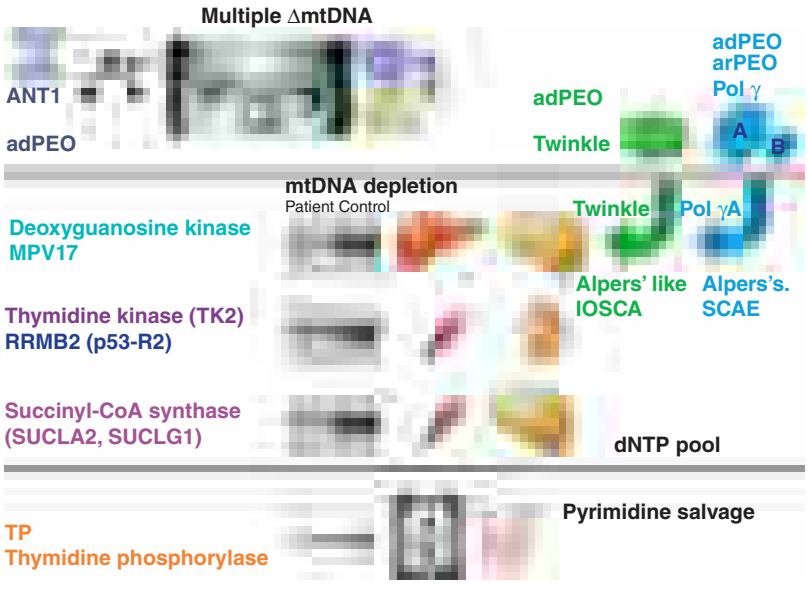

FIGURE 472-10 Disorders associated with perturbations in nuclear-mitochondrial genomic cross-talk. Clinical features and genes associated with multiple mitochondrial DNA (mtDNA) deletions, mtDNA depletion, and mitochondrial neurogastrointestinal encephalomyopathy syndromes. ANT, adenine nucleotide translocators; adPEO, autosomal dominant progressive external ophthalmoplegia; arPEO, autosomal recessive progressive external ophthalmoplegia; IOSCA, infantile-onset spinocerebellar ataxia; SCAE, spinocerebellar ataxia and epilepsy. *(Reproduced with permission from A Spinazzola, M Zeviani: Disorders from perturbations of nuclear-mitochondrial intergenomic cross-talk. J Intern Med 265:174, 2009.)*

common mtDNA variants and human health and disease phenotypes or adaptation to different environmental influences (e.g., climate), a word of caution is in order.

Many studies that purport to show such associations with phenotypes such as longevity, athletic performance, and metabolic and neurodegenerative disease are limited by small sample sizes, possible genotyping inaccuracies, and the possibility of population stratification or ethnic ancestry bias. Because mtDNA haplogroups are so prominently partitioned along phylogeographic lines, it is difficult to exclude the possibility that a haplogroup for which an association has been found is simply a marker for differences in populations with a societal or environmental difference or with different allele frequencies at other genomic loci, which are actually causally related to the heritable trait or disease of interest. The difficulty in generating cellular or animal models to test the functional influence of homoplasmic sequence variants (as a result of mtDNA polyploidy) further compounds the challenge. The most likely formulation is that the risk conferred by different mtDNA haplogroup-defining homoplasmic mutations for common diseases depends on the concomitant nuclear genomic background, together with environmental influences. Progress in minimizing potentially misleading associations in mtDNA heritable trait and disease studies should include ensuring adequate sample size taken from a large sample recruitment base, using carefully matched controls and population structure determination, and performing analysis that takes into account epistatic interactions with other genomic loci and environmental factors.

IMPACT OF ACQUIRED SOMATIC mtDNA MUTATION ON HUMAN HEALTH AND DISEASE

Studies on aging humans and animals have shown a potentially important correlation of age with the accumulation of heterogeneous mtDNA mutations, especially in those organ systems that undergo the most prominent age-related degenerative tissue phenotype. Sequencing of PCR-amplified single mtDNA molecules has demonstrated an average of two to three point mutations per molecule in elderly subjects when compared with younger ones. Point mutations observed include those responsible for known heritable heteroplasmic mtDNA disorders, such as the m.3344A>G and m.3243A>G mutations responsible for the MERRF and MELAS syndromes, respectively. However, the cumulative burden of these acquired somatic point mutations with age was observed to remain well below the threshold expected for phenotypic expression (<2%). Point mutations at other sites not normally involved in inherited mtDNA disorders have also been shown to accumulate to much higher levels in some tissues of elderly individuals, with the description of tissue-specific "hot spots" for acquired somatic mtDNA point mutations. Along the same lines, an age-associated and tissue-specific accumulation of mtDNA deletions has been observed, including deletions involved in known heritable mtDNA disorders, as well as others. The accumulation of functional mtDNA deletions in a given tissue is expected to be associated with mitochondrial dysfunction, as reflected in an age-associated patchy and reduced COX activity on histochemical staining, especially in skeletal and cardiac muscle and brain. A particularly well-studied and potentially important example is the accumulation of mtDNA deletions and COX deficiency observed in neurons of the substantia nigra in Parkinson's disease patients.

The progressive accumulation of ROS has been proposed as the key factor connecting mtDNA mutations with aging and age-related disease pathogenesis **(Fig. 472-11)**. As noted above, ROS are a by-product of oxidative phosphorylation and are removed by detoxifying antioxidants into less harmful moieties; however, exaggerated production of ROS or impaired removal results in their accumulation. One of the main targets for ROS-mediated injury is DNA, and mtDNA is particularly vulnerable because of its proximity to the origin of free radical production, the lack of protective histones, and less efficient injury repair systems compared with nuclear DNA. In turn, accumulation of mtDNA mutations results in inefficient oxidative phosphorylation, with the potential for excessive production of ROS, generating a "vicious cycle" of cumulative mtDNA damage. Indeed, measurement

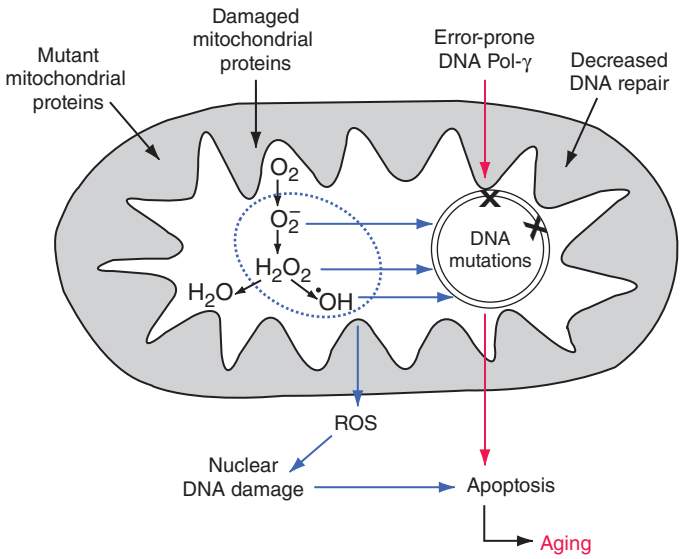

FIGURE 472-11 Multiple pathways of mitochondrial DNA (mtDNA) damage and aging. Multiple factors may impinge on the integrity of mitochondria that lead to loss of cell function, apoptosis, and aging. The classic pathway is indicated with *blue arrows*; the generation of reactive oxygen species (ROS; superoxide anion, hydrogen peroxide, and hydroxyl radicals), as a by-product of mitochondrial oxidative phosphorylation, results in damage to mitochondrial macromolecules, including the mtDNA, with the latter leading to deleterious mutations. When these factors damage the mitochondrial energy-generating apparatus beyond a functional threshold, proteins are released from the mitochondria that activate the caspase pathway, leading to apoptosis, cell death, and aging. *(Reproduced with permission from L Loeb et al: The mitochondrial theory of aging and its relationship to reactive oxygen species damage and somatic mtDNA mutations. Proc Natl Acad Sci USA 102:18769, 2005.)*

of the oxidative stress biomarker 8-hydroxy-2-deoxyguanosine has been used to measure age-dependent increases in mtDNA oxidative damage at a rate exceeding that of nuclear DNA. It should be noted that mtDNA mutations can potentially occur in postmitotic cells as well, because mtDNA replication is not synchronized with the cell cycle. Two other proposed links between mtDNA mutation and aging, besides ROS-mediated tissue injury, are the perturbations in efficiency of oxidative phosphorylation with disturbed cellular aerobic function and perturbations in apoptotic pathways, whose execution steps involve mitochondrial activity.

Genetic intervention studies in animal models have sought to clarify the potential causative relationship between acquired somatic mtDNA mutation and the aging phenotype, and the role of ROS in particular. Replication of the mitochondrial genome is mediated by the activity of the nuclear-encoded *POLG*. A transgenic homozygous mouse knock-in mutation of this gene renders the polymerase enzyme deficient in proofreading and results in a threefold to fivefold increase in mtDNA mutation rate. Such mice develop a premature aging phenotype, which includes subcutaneous lipoatrophy, alopecia, kyphonia, and weight loss with premature death. Although the finding of increased mtDNA mutation and mitochondrial dysfunction with age has been solidly established, the causative role and specific contribution of mitochondrial ROS to aging and age-related disease in humans has yet to be proved. Similarly, although many tumors display higher levels of heterogeneous mtDNA mutations, a causal relationship to tumorigenesis has not been proved.

Besides the age-dependent acquired accumulation in somatic cells of heterogeneous point mutations and deletions, a quite different effect of nonheritable and acquired mtDNA mutation has been described affecting tissue stem cells. In particular, disease phenotypes attributed to acquired mtDNA mutation have been observed in sporadic and apparently nonfamilial cases involving a single individual or even tissue, usually skeletal muscle. The presentation consists of decreased exercise tolerance and myalgias, sometimes progressing to rhabdomyolysis. As in the case of the sporadic, heteroplasmic, large-scale deletion, classic syndromes of chronic PEO, Pearson syndrome, and KSS, the

absence of a maternal inheritance pattern, together with the finding of limited tissue distribution, suggest a molecular pathogenic mechanism emanating from mutations arising de novo in muscle stem cells after germline differentiation (somatic mutations that are not sporadic and occur in tissue-specific stem cells during fetal development or in the postnatal maintenance or postinjury repair stage). Such mutations would be expected to be propagated only within the progeny of that stem cell and affect a particular tissue within a given individual, without evidence of heritability.

PROSPECTS FOR CLINICAL MANAGEMENT OF mtDNA DISEASE

TREATMENT OF mtDNA DISORDERS

No specific curative treatment for mtDNA disorders is currently available; therefore, the management of mitochondrial disease is largely supportive. Management issues may include early diagnosis and treatment of epilepsy, gastrointestinal dysfunction, diabetes mellitus, cardiac pacing, ptosis correction, and intraocular lens replacement for cataracts. Less specific interventions in the case of other disorders involve combined treatment strategies including dietary intervention and removal of toxic metabolites. Cofactors and vitamin supplements are widely used in the treatment of diseases of mitochondrial oxidative phosphorylation, although there is little evidence, apart from anecdotal reports, to support their use. This includes administration of artificial electron acceptors, including vitamin K_3, vitamin C, and ubiquinone (coenzyme Q10); administration of cofactors (coenzymes) including riboflavin, carnitine, and creatine; and use of oxygen radical scavengers, such as vitamin E, copper, selenium, ubiquinone, and idebenone. Drugs that could interfere with mitochondrial function, such as the anesthetic agent propofol, barbiturates, and high doses of valproate, should be avoided. The use of valproate in patients with pathogenic mutations in *POLG* and possibly other mutations affecting mtDNA stability and replication are especially contraindicated. Supplementation with the nitric oxide synthase substrate, L-arginine, and more recently L-citrulline has been advocated as a vasodilator treatment during stroke-like episodes as well as for chronic management in patients with MELAS. Open label studies demonstrate that levoarginine and levocitrulline may be helpful in reducing the stroke-like symptoms in MELAS, but may have serious side effects. As CSF folate deficiency has been reported in some cases of mitochondrial disease, this can be treated with folinic acid.

The physician should also be familiar with environmental interactions, such as the strong and consistent association between visual loss in LHON and smoking or ethanol consumption. A clinical penetrance of 93% was found in men who smoked. Asymptomatic carriers of an LHON mtDNA mutation should, therefore, be strongly advised not to smoke and to moderate their alcohol intake. Although not a cure, these interventions might stave off the devastating clinical manifestations of the LHON mutation. Another example is strict avoidance of aminoglycosides in the familial syndrome of ototoxic susceptibility to aminoglycosides in the presence of the mtDNA m.1555A>G mutation of the 12SrRNA encoding gene.

Clinical trials using novel agents are currently being conducted and analyzed. These include α-tocotrienol (EPI-743, BioElectron Technology Corporation), cysteamine bitartrate (RP-103, Horizon Pharma), omaveloxolone (RTA-408, Reata Pharma), and elamipretide (Stealth Biotheraputics). In an open label study of α-tocotrienol used to treat 10 children with Leigh syndrome, there were improvements in the primary endpoints including the Newcastle Pediatric Mitochondrial Diseases Scale, the Gross Motor Function Measure, and the PedsQL Neuromuscular Module. Ongoing studies continue for α-tocotrienol in children, and both omaveloxolone and elamipritide in adults with primary mitochondrial myopathy.

GENETIC COUNSELING, PRENATAL DIAGNOSIS, AND PGD IN mtDNA DISORDERS

The provision of accurate genetic counseling and reproductive options to families with mtDNA mutations is challenging due to the unique genetic features of mtDNA inheritance that distinguish it from Mendelian genetics. mtDNA defects are transmitted by maternal inheritance. mtDNA de novo mutations are often large deletions, affect one family member, and usually represent no significant risk to other members of the family. In contrast, mtDNA point mutations or duplications can be transmitted down the maternal line. Accordingly, the father of an affected individual has no risk of harboring the disease-causing mutation, and a male cannot transmit the mtDNA mutation to his offspring. In contrast, the mother of an affected individual usually harbors the same mutation but might be completely asymptomatic. This wide phenotypic variability is primarily related to the phenomena of heteroplasmy and the mutation load carried by different members of the same family. Consequently, a symptomatic or asymptomatic female harboring a disease-causing mutation in a heteroplasmic state will transmit to her offspring variable amounts of the mutant mtDNA molecules. The offspring will be symptomatic or asymptomatic primarily according to the mutant load transmitted via the oocyte and, to some extent, subsequent mitotic segregation during development. Interactions with the mtDNA haplotype background or nuclear human genome (as in the case of LHON) serve as an additional important determinant of disease penetrance. Because the severity of the disease phenotype associated with the heteroplasmic mutation load is a function of the stochastic differential segregation and copy number of mutant mtDNA during the oogenesis bottleneck and, subsequently, following tissue and organ development in the offspring, it is rarely predictable with any degree of accuracy. For this reason, prenatal diagnosis (PND) and PGD techniques that have evolved into integral and well-accepted standards of practice are severely hampered in the case of mtDNA-related diseases.

The value of PND and PGD is limited, partly due to the absence of data on the rules that govern the segregation of wild-type and mutant mtDNA species (heteroplasmy) among tissue in the developing embryo. Three factors are required to ensure the reliability of PND and PGD: (1) a close correlation between the mutant load and the disease severity, (2) a uniform distribution of mutant load among tissues, and (3) no major change in mutant load with time. These criteria are suggested to be fulfilled for the NARP m.8993T>G mutation but do not seem to apply to other mtDNA disorders. In fact, the level of mutant mtDNA in a chorionic villous or amniotic fluid sample may be very different from the level in the fetus, and it would be difficult to deduce whether the mutational load in the prenatal samples provides clinically useful information regarding the postnatal and adult state.

PREVENTION OF MITOCHONDRIAL DISEASE INHERITANCE BY ASSISTED REPRODUCTIVE TECHNOLOGIES

Because the treatment options for patients with mitochondrial disease are rather limited, with no current U.S. Food and Drug Administration (FDA) approved therapies for established mitochondrial DNA disease, preventive interventions that eliminate the likelihood of transmission of affected mtDNA into offspring are desirable. The poor reliability of prenatal and preimplantation approaches in predicting mitochondrial DNA disease has resulted in the search for alternative preventive approaches. The common purpose underlying various emerging approaches is to reduce mutant heteroplasmy levels to a level below a pathogenic threshold. This is based on the observed relationship between heteroplasmy and disease inheritance patterns, which indicates that even a small increase in copy number of nonmutant mtDNA molecules in the fertilized egg can exceed the threshold required to ameliorate serious clinical disease. Use of gene editing, with Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) technology for example, to shift the heteroplasmy load in affected tissues will require future development of corrective gene delivery techniques. Likewise, induced pluripotent cell technology has not yet met with widespread success in the preclinical research setting. This has prompted the application of Mitochondrial Replacement Therapy (MRT) approaches **(Fig. 472-12)**. Both of these approaches substitute in vitro the entire oocyte or zygote complement of mitochondria, together with their mtDNA from the carrier mother, with the

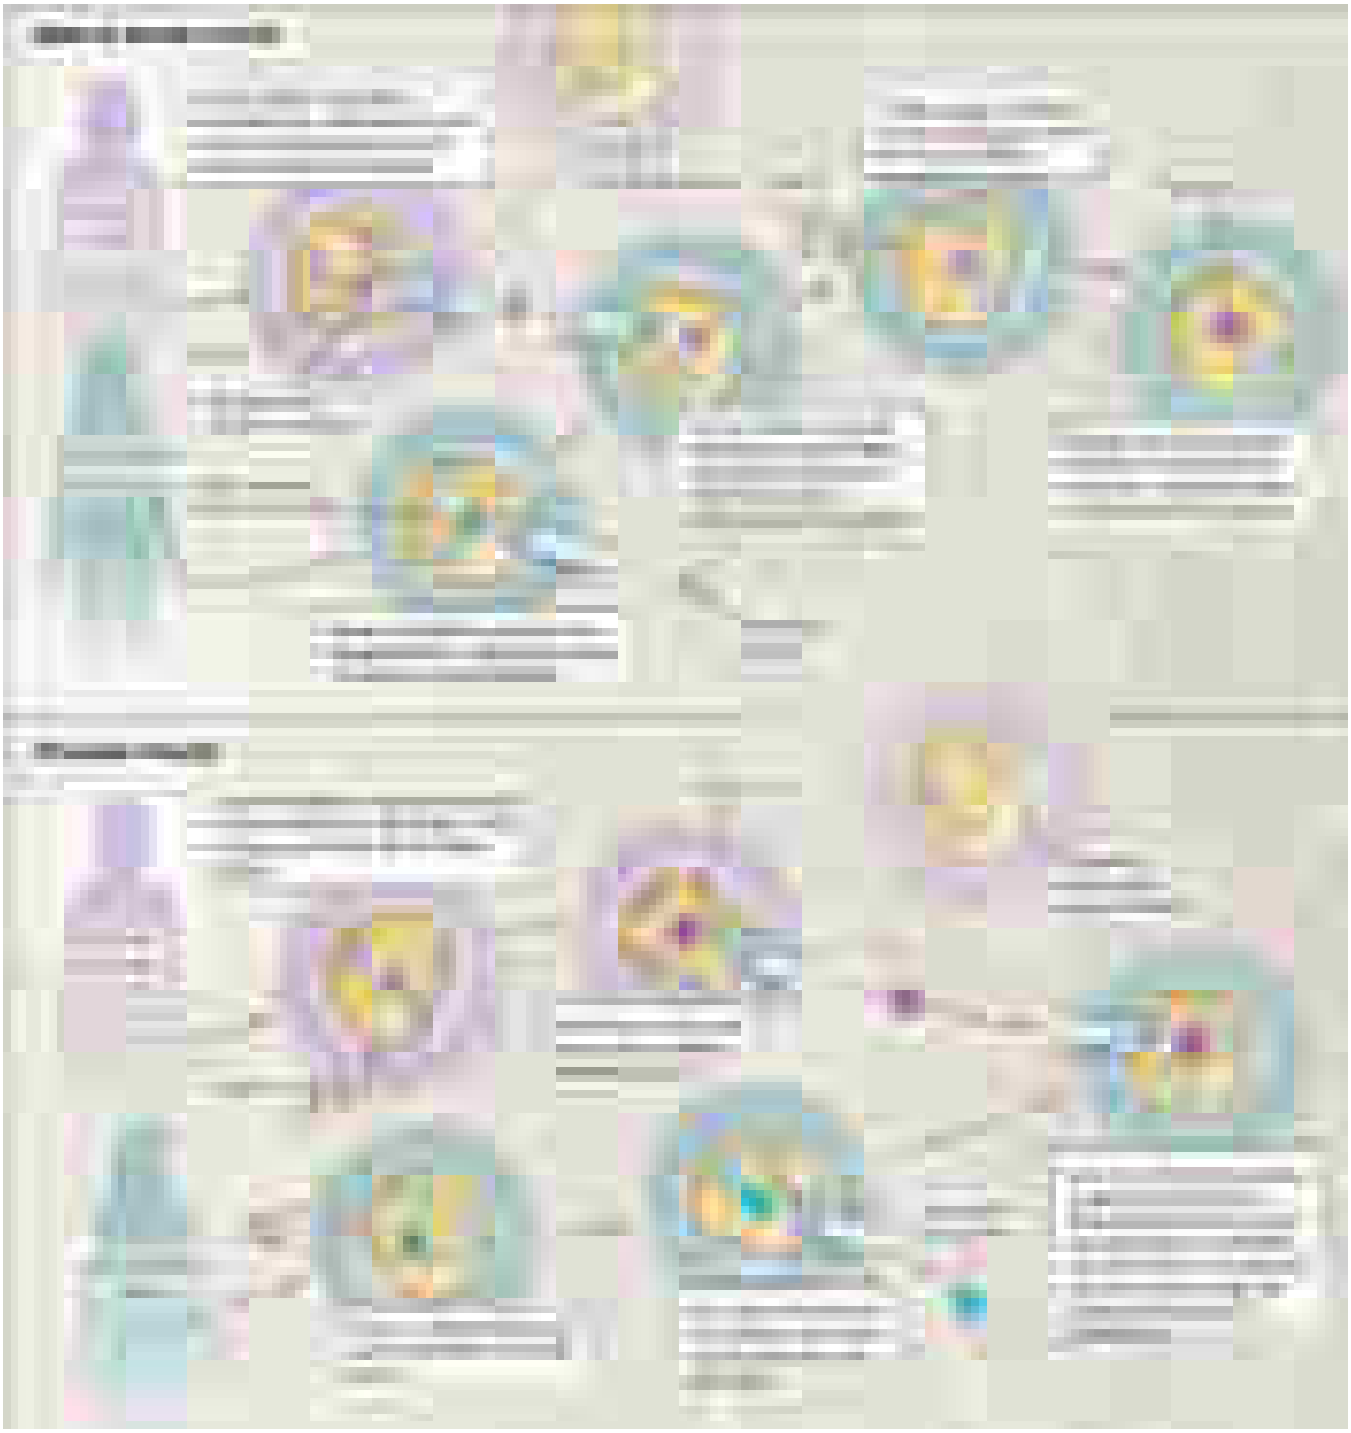

FIGURE 472-12 Mitochondrial replacement techniques—maternal spindle transfer and pronuclear transfer. In both procedures, some mutant mtDNA, estimated at 1–2%, might be carried over together with the spindle or pronucleus, but the levels are low enough to avoid disease risk. IVF denotes in vitro fertilization. *(Used with permission from MJ Falk et al: Mitochondrial Replacement Techniques–Implications for the Clinical Community. N Engl J Med 374: 1103, 2016.)*

unaffected complement of mitochondria and their unaffected mtDNA from a donor woman. This can be accomplished either by removing and transferring the carrier mother's spindle with her nuclear DNA into the unfertilized oocyte of the donor, or alternatively by transferring the pronucleus from the fertilized oocyte of the carrier mother to the unfertilized donor oocyte from which the pronucleus has been removed. Both of these approaches provide a "bulk" substitution and hence do not target the specific mtDNA mutation, and are potentially applicable to a wide variety of mtDNA disorders. This is a form of germline genetic therapy, and therefore projects onto future generations in the case of a female offspring. Accordingly, ethical and regulatory bodies have appropriately weighed in on the societal implications of such approaches, and have been tentatively supportive of human clinical investigation for situations of preventing great suffering and when the clinical need is clear and unambiguous, subject to specified conditions and principles and subject to ethical scrutiny. Several such studies have been initiated, and careful examination and follow up are needed to determine developmental and longer-term health and fertility of children who had undergone genetic manipulation at the earliest stages of human development, and whose genomes comprise separate maternal origins of nuclear and mtDNA genomes. It has been recommended that such studies be limited to male offspring, who cannot then transmit the donor mtDNA to future generations, until such time as the health, ethical, and societal issues are well understood, and live up to the exciting promise of reducing the burden of clinical mtDNA disease in the future.

473 Applications of Stem Cell Biology in Clinical Medicine

John A. Kessler

Damage to an organ initiates a series of events that lead to the reconstruction of the damaged tissue, including proliferation, differentiation, and migration of various cell types; release of cytokines and chemokines; and remodeling of the extracellular matrix. Endogenous stem and progenitor cells are among the cell populations that are involved in these injury responses. In normal steady-state conditions, an equilibrium is maintained in which endogenous stem cells intrinsic to the tissue replenish dying cells. After tissue injury, stem cells in organs such as the liver and skin have a remarkable ability to regenerate the organ, whereas other stem cell populations, such as those in the heart and brain, have a much more limited capability for self-repair. In rare circumstances, circulating stem cells may contribute to regenerative responses by migrating into a tissue and differentiating into organ-specific cell types. The goal of stem cell therapies is to promote cell replacement in organs that are damaged beyond their ability to self-repair.

GENERAL STRATEGIES FOR STEM CELL REPLACEMENT

At least three different therapeutic concepts for cell replacement can be envisaged **(Fig. 473-1)**. One therapeutic approach involves direct administration of stem cells. The cells may be injected directly into the damaged organ, where they can differentiate into the desired cell type. Alternatively, stem cells may be injected systemically since they have the capacity to home in on damaged tissues by following gradients of cytokines and chemokines released by the diseased organ. A second approach involves transplantation of differentiated cells derived from stem cells. For example, pancreatic islet cells can be generated from stem cells before transplantation into diabetic patients, and cardiomyocytes can be generated to heart disease. A third approach involves stimulation of endogenous stem cells to facilitate repair. This goal might be accomplished by administration of appropriate growth factors and drugs that amplify the number of endogenous stem/progenitor cells and/or direct them to differentiate into the desired cell types. Therapeutic stimulation of precursor cells is already a clinical reality in the hematopoietic system, where factors such as erythropoietin, granulocyte colony-stimulating factor, and granulocyte-macrophage colony-stimulating factor are used to increase production of specific blood elements. In addition to these strategies for cell replacement, a number of other approaches could involve stem cells for ex vivo or in situ generation of tissues, a process termed tissue engineering. Stem cells are excellent candidates as vehicles for cellular gene therapy **(Chap. 458)**, and they also potentially can be used to modify immune responses. Finally, transplanted stem cells may exert paracrine effects to promote repair of damaged tissues without differentiating to replace lost cells.

Stem cell transplantation is not a new concept but rather is already part of established medical practice. Hematopoietic stem cells (HSCs) **(Chap. 92)** are responsible for the long-term repopulation of all blood elements in recipients of bone marrow transplants, and hematopoietic stem cell transplantation is the gold standard against which other stem cell transplantation therapies will be measured. Transplantation of differentiated cells is also a clinical reality, and donated organs and tissues are often used to replace damaged tissues. However, the need for transplantable tissues and organs far outweighs the available supply, and organ transplantation has limited potential for some tissues, such as the brain. Stem cells offer the possibility of a renewable source of replacement cells for virtually all organs.

SOURCES OF STEM CELLS FOR TISSUE REPAIR

A variety of different types of stem cells could be used in regenerative strategies, including embryonic stem (ES) cells, induced pluripotent stem (iPS) cells, umbilical-cord blood stem cells (USCs), organ-specific

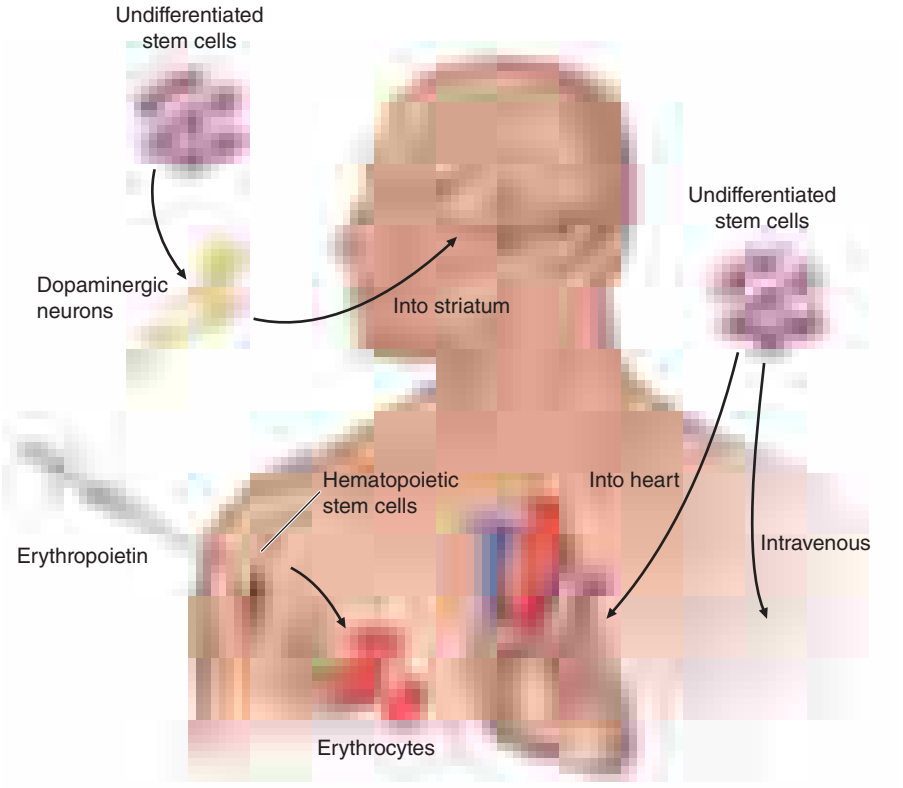

FIGURE 473-1 Strategies for transplantation of stem cells. 1. Undifferentiated or partially differentiated stem cells may be injected directly into the target organ or intravenously. 2. Stem cells may be differentiated ex vivo before injection into the target organ. 3. Growth factors or other drugs may be injected to stimulate endogenous stem cell populations.

somatic stem cells (e.g., neural stem cells for treatment of the brain), and somatic stem cells that generate cell types specific for the target organ rather than the donor organ (e.g., bone marrow mesenchymal stem cells [MSCs] or CD34+ HSCs for cardiac repair). Although each cell type has potential advantages and disadvantages, there are a number of generic challenges associated with developing any of these cell types into a useful and reliable clinical tool.

Embryonic Stem Cells ES cells have the potential to generate all of the cell types in the body; thus, in theory, there are no restrictions on the organs that could be regenerated. ES cells can self-renew endlessly, so that a single cell line with carefully characterized traits potentially could generate almost limitless numbers of cells. In the absence of moral or ethical constraints (see "Ethical Issues," below), unused human blastocysts from fertility clinics could be used to derive new ES cell lines that are matched immunologically with potential transplant recipients. Alternatively, somatic cell nuclear transfer ("therapeutic cloning") could be used to create ES cell lines that are genetically identical to those of the patient, although this endeavor has been technically refractory for human cells. However, human ES cells are difficult to culture and grow slowly. Techniques for differentiating them into specific cell types are just beginning to be developed. Cells tend to develop abnormal karyotypes and other abnormalities with increased time in culture, and ES cells have the potential to form teratomas if all cells are not committed to the desired cell types before transplantation. Further, human ES cells are ethically controversial and, on these grounds, their use would be unacceptable to some patients and physicians despite their therapeutic potential. Nevertheless, there have been limited clinical trials of ES-derived cells in a number of disorders, including macular degeneration, myopia, heart failure, diabetes, and spinal cord injury (SCI).

Induced Pluripotent Stem Cells The field of stem cell biology was transformed by the discovery that adult somatic cells can be converted ("reprogrammed") into pluripotent cells through the overexpression of four transcription factors normally expressed in pluripotent cells. These iPS cells share most properties with ES cells, although there are distinct differences in gene expression between ES and iPS cells. The initial use of viruses to insert the transcription factors into somatic cells made the resulting cells unsuitable for clinical use. However, a number of strategies have since been developed to circumvent this problem, including the insertion of modified mRNAs, proteins, or microRNAs rather than cDNAs and treatment with small molecules; the use of non-integrating viruses such as Sendai virus; the insertion of transposons with the programming factors, followed by their subsequent removal; and the use of floxed viral constructs, followed by treatment with Cre recombinase to excise those constructs. iPS cells derived from patients with different disorders are currently being used extensively for disease modeling and drug discovery. However, the safety of iPS cells for use in regenerative strategies in humans remains to be demonstrated. The first clinical trial in macular degeneration was suspended after treatment of one patient because of discovery of a mutation in cells derived for the second patient, but it is scheduled to resume. Potential advantages of iPS cells are that somatic cells from patients would generate pluripotent cells genetically identical to those of the patient, and that these cells are not subject to the same ethical constraints as ES cells. It is not clear whether the differences in gene expression between ES and iPS cells will have any impact on their potential clinical utility, and studies of both cell types will be needed to resolve this issue.

Umbilical-Cord Stem Cells USCs are widely available. These cells appear to be associated with less graft-versus-host disease than are some other cell types, such as marrow stem cells. They have less human leukocyte antigen restriction than adult marrow stem cells and are less likely to be contaminated with herpesvirus. However, it is unclear how many different cell types can be generated from USCs, and methods for differentiating these cells into non-hematopoietic phenotypes are largely lacking. Nevertheless, there are ongoing clinical trials of these cells in dozens of disorders, including cirrhosis, cardiomyopathies, multiple sclerosis, burns, stroke, autism, and critical limb ischemia.

Organ-Specific Multipotent Stem Cells Organ-specific multipotent stem cells have the advantage of already being somewhat specialized so that the inducement of desired cell types may be easier. Cells potentially could be obtained from the patient and amplified in cell culture, circumventing the problems associated with immune rejection. Stem cells are relatively easy to harvest from some tissues, such as bone marrow and blood, but are difficult to harvest from other tissues, such as heart and brain. Moreover, these populations of cells are more limited in potentiality than are pluripotent ES or iPS cells, and they may be difficult to obtain in large quantities from many organs. Therefore, substantial efforts have been devoted to developing techniques for using more easily obtainable stem cell populations, such as bone marrow MSCs, CD34+ HSCs, cardiac mesenchymal cells, and adipose-derived stem cells (ASCs), for use in regenerative strategies. Tissue culture evidence suggests that these stem cell populations may be able to generate differentiated cell types unrelated to their organ source (including myocytes, chondrocytes, tendon cells, osteoblasts, cardiomyocytes, adipocytes, hepatocytes, and possibly neurons) in a process known as *transdifferentiation*. However, it is still unclear whether these stem cells are capable of generating differentiated cell types that integrate into organs, survive, and function after transplantation in vivo. A number of early studies of MSCs transplanted into heart, liver, and other organs suggested that the cells had differentiated into organ-specific cell types with beneficial effects in animal models of disease. Unfortunately, subsequent studies revealed that the stem cells had simply fused with cells resident in the organs and that the observed beneficial effects were due to paracrine release of trophic and anti-inflammatory cytokines. Further studies will be necessary to determine whether transdifferentiation of MSCs, ASCs, or other stem cell populations occurs at a high enough frequency to make these cells useful for stem cell replacement therapy. Despite the remaining issues, clinical trials of MSCs, autologous HSCs, USCs, and ASCs are being performed in many disorders, including ischemic cardiac disease, cardiomyopathy, diabetes, stroke, cirrhosis, amyotrophic lateral sclerosis (ALS), and muscular dystrophy. Another approach has been to derive organ-specific stem cells by parthenogenesis, and a clinical trial of neural stem cells derived this way has begun for Parkinson's disease.

Regardless of the source of the stem cells used in regenerative strategies, a number of generic problems must be overcome for the development of successful clinical applications. Methods must be devised to reliably generate large numbers of specific cell types, to minimize the risk of tumor formation or proliferation of inappropriate cell types, to ensure the viability and function of the engrafted cells, to overcome immune rejection when autografts are not used, and to facilitate revascularization of regenerated tissue. Each organ system also will pose tissue-specific problems for stem cell therapies.

DISEASE-SPECIFIC APPLICATIONS OF STEM CELLS

Ischemic Heart Disease and Cardiomyocyte Regeneration Because of the high prevalence of ischemic heart disease, extensive efforts have been devoted to the development of strategies for stem cell replacement of cardiomyocytes. Historically, the adult heart has been viewed as a terminally differentiated organ without the capacity for regeneration. However, recent studies have demonstrated that the heart has the capacity for low levels of cardiomyocyte regeneration (Chap. 232). This regeneration appears to be accomplished by cardiac stem cells resident in the heart and possibly also by cells originating in the bone marrow. The heart might be an ideal source of stem cells for therapeutic use, but techniques for isolating, characterizing, and amplifying large numbers of these cells have not yet been perfected. For successful myocardial repair, stem cell therapy must deliver cells either systemically or locally, and the cells must survive, engraft, and differentiate into functional cardiomyocytes that couple mechanically and electrically with the recipient myocardium. The optimal method for cell delivery is not clear, and various experimental and clinical studies have successfully employed intramyocardial, transendocardial, intravenous, intracoronary, and retrograde coronary venous injections. In experimental myocardial infarction, functional improvements have

been achieved after transplantation of a variety of different cell types, including ES cells, HSCs, MSCs, USCs, and ASCs. Early studies suggested that each of these cell types might have the potential to engraft and generate cardiomyocytes. However, most investigators have found that the generation of new cardiomyocytes by these cells is at best a rare event and that graft survival over long periods is poor. The preponderance of evidence suggests that the observed beneficial effects of most experimental therapies were not derived from direct stem cell generation of cardiomyocytes but rather from indirect effects of the stem cells on resident cells. It is not clear whether these effects reflect the release of soluble trophic factors, the induction of angiogenesis, the release of anti-inflammatory cytokines, or another mechanism. A wide variety of cell delivery methods, cell types, and cell doses have been used in a progressively enlarging series of clinical trials, but the fate of the cells and the mechanisms by which they alter cardiac function are still open questions. In aggregate, however, these studies have shown a small but measurable improvement in cardiac function and, in some cases, reduction in infarct size. Further, transplantation of bone marrow-derived stem cells improved outcome for patients in heart failure. In short, the available evidence suggests that the beneficial clinical impact reflects an indirect effect of the transplanted cells rather than cell replacement. However, genuine cell replacement may become possible as new protocols are being developed for generating cardiomyocytes from pluripotent and multipotent stem cells.

Diabetes Successes with islet cell and pancreas transplantation have provided proof of concept for cell-based therapies for type 1 diabetes. However, the demand for donor pancreases far exceeds the number available, and maintenance of long-term graft survival remains a problem. The search for a renewable source of stem cells capable of regenerating pancreatic islets has therefore been intensive. Pancreatic beta cell turnover occurs even in the normal pancreas, although the source of the new beta cells remains controversial. This persistent turnover suggests that, in principle, it should be possible to develop strategies for reconstituting the beta cell population in diabetics. Attempts to devise techniques for promoting endogenous regenerative processes by using combinations of growth factors, drugs, and gene therapy have failed thus far, but this remains a potentially viable approach. A number of different cell types are candidates for use in stem cell replacement strategies, including iPS cells, ES cells, hepatic progenitor cells, pancreatic ductal progenitor cells, and MSCs. Successful therapy will depend on the development of a source of cells that can be amplified to produce large numbers of progeny with the ability to synthesize, store, and release insulin when it is required, primarily in response to changes in the ambient level of glucose. The proliferative capacity of the replacement cells must be tightly regulated to avoid excessive expansion of beta cell numbers and the consequent development of hyperinsulinemia/hypoglycemia; moreover, the cells must withstand immune rejection. Although ES and iPS cells can be differentiated into cells that produce insulin, these cells have a lower content of insulin and a higher rate of apoptosis than pancreatic beta cells, and generally lack the capacity to fully normalize blood glucose levels in diabetic animals. However, clinical trials of encapsulated ES cell-derived pancreatic progenitor cells are currently in progress.

During embryogenesis, the pancreas, liver, and gastrointestinal tract are all derived from the anterior endoderm, and transdifferentiation of pancreas to liver and vice versa has been observed in a number of pathologic conditions. There is also substantial evidence that multipotential stem cells reside within gastric glands and intestinal crypts. These observations suggest that hepatic, pancreatic, and/or gastrointestinal precursor cells may be reasonable candidates for cell-based therapy for diabetes, although it is unclear whether insulin-producing cells derived from pancreatic stem cells or liver progenitors can be expanded in vitro to clinically useful numbers. MSCs and neural stem cells both reportedly have the capacity to generate insulin-producing cells, but there is no convincing evidence that either cell type will be clinically useful. Clinical trials of MSCs, USCs, HSCs, and ASCs in both type 1 and type 2 diabetes are ongoing.

Nervous System Substantial progress has been made in the development of methodologies for generating neural cells from different stem cell populations. Human ES or iPS cells can be induced to generate cells with the properties of neural stem cells, and these cells in turn give rise to neurons, oligodendroglia, and astrocytes. Reasonably large numbers of these cells can be transplanted into the rodent brain with formation of appropriate cell types and no tumor formation. Multipotent stem cells present in the adult brain also can be easily amplified in number and used to generate all the major neural cell types, but the need for invasive procedures to obtain autologous cells is a major limitation. Fetal neural stem cells derived from miscarriages or abortions are an alternative but raise ethical concerns. Nevertheless, clinical trials of fetal neural stem cells have commenced in ALS, stroke, and several other disorders. Transdifferentiation of MSCs and ASCs into neural stem cells, and vice versa, has been reported by numerous investigators, and clinical trials of such cells have begun for a number of neurologic diseases. Clinical trials of a conditionally immortalized human cell line and of USCs in stroke are also in progress. Because of the incapacitating nature of neural disorders and the limited endogenous repair capacity of the nervous system, clinical trials of stem cells in neurologic disorders have been particularly numerous, including trials in SCI, multiple sclerosis, epilepsy, Alzheimer's disease, ALS, acute and chronic stroke, numerous genetic disorders, traumatic brain injury, Parkinson's disease, and others. In diseases such as ALS, possible benefits are more likely to be due to indirect trophic effects than to neuron replacement. In Parkinson's disease, the major motor features of the disorder result from the loss of a single cell population: dopaminergic neurons within the substantia nigra; this circumstance suggests that cell replacement should be relatively straightforward. However, two clinical trials of fetal nigral transplantation failed to meet their primary endpoint and were complicated by the development of dyskinesia. Transplantation of stem cell–derived dopamine-producing cells offers a number of potential advantages over the fetal transplants, including the ability of stem cells to migrate and disperse within tissue, the potential for engineering regulatable release of dopamine, and the ability to engineer cells to produce factors that will enhance cell survival. Nevertheless, the experience with fetal transplants points out the difficulties that may be encountered.

At least some of the neurologic dysfunction after SCI reflects demyelination, and both ES cells and MSCs can facilitate remyelination after experimental SCI. Clinical trials of MSCs in this disorder have commenced in a number of countries, and SCI was the first disorder targeted for the clinical use of ES cells. The first trial of ES cell derived oligodendroglial progenitor cells in SCI was terminated early for nonmedical reasons, but another trial has commenced. At present, no population of transplanted stem cells has been shown to have the capacity to generate neurons that extend axons over long distances to form synaptic connections (as would be necessary for replacement of upper motor neurons in ALS, stroke, or other disorders). For many injuries, including SCI, the balance between scar formation and tissue repair/regeneration may prove to be an important consideration. For example, it may ultimately prove necessary to limit scar formation so that axons can reestablish connections.

Liver Liver transplantation is currently the only successful treatment for end-stage liver diseases, but the shortage of liver grafts limits its application. Clinical trials of hepatocyte transplantation demonstrate its potential as a substitute for organ transplantation, but this approach is limited by the paucity of available cells. Potential sources of stem cells for regenerative strategies include endogenous liver stem cells (such as oval cells), ES cells, MSCs, and USCs. Although a series of studies in humans as well as animals suggested that transplanted MSCs and HSCs can generate hepatocytes, fusion of the transplanted cells with endogenous liver cells, giving the erroneous appearance of new hepatocytes, appears to be the underlying event in most circumstances. The available evidence suggests that transplanted HSCs and MSCs can generate hepatocyte-like cells in the liver only at a very low frequency, but there are beneficial consequences presumably related to indirect paracrine effects. ES cells can be differentiated into hepatocytes

and transplanted in animal models of liver failure without the formation of teratomas. Clinical trials are in progress in cirrhosis with numerous cell types, including MSCs, USCs, HSCs, and ASCs.

Other Organ Systems and the Future The use of stem cells in regenerative strategies has been studied for many other organ systems and cell types, including skin, eye, cartilage, bone, kidney, lung, endometrium, vascular endothelium, smooth muscle, and striated muscle, and clinical trials in these and other organs are ongoing. In fact, the potential for stem cell regeneration of damaged organs and tissues is virtually limitless. However, numerous obstacles must be overcome before stem cell therapies can become a widespread clinical reality. Only HSCs have been adequately characterized by surface markers so that they can be unambiguously identified, a prerequisite for reliable clinical applications. The pathways for differentiating stem cells into specific cellular phenotypes are largely unknown, and the ability to control the migration of transplanted cells or predict the response of the cells to the environment of diseased organs is presently limited. Some strategies may employ the coadministration of scaffolding, artificial extracellular matrix, and/or growth factors to orchestrate differentiation of stem cells and their organization into appropriate constituents of the organ. There is currently no way to image stem cells in vivo after transplantation into humans, and it will be necessary to develop techniques to do so. Fortunately, stem cells can be engineered before transplantation to contain a contrast agent that may make in vivo imaging feasible. The potential for tumor formation and the problems associated with immune rejection are impediments, and it will also be necessary to develop techniques for ensuring vascularization of regenerated tissues. There already are many strategies for supporting cell replacement, including coadministration of vasoactive endothelial growth factor to foster vascularization of the transplant. Some strategies also include the genetic engineering of stem cells with an inducible suicide gene so that the cells can be easily eradicated in the event of tumor formation or another complication. The potential for stem cell therapies to revolutionize medical care is extraordinary, and disorders such as myocardial infarction, diabetes, and Parkinson's disease, among many others, are potentially curable by such therapies. However, stem cell–based therapies are still at a very early stage of development, and perfection of techniques for clinical transplantation of predictable, well-characterized cells is going to be a difficult and lengthy undertaking.

ETHICAL ISSUES

Stem cell therapies raise ethical and socially contentious issues that must be addressed in parallel with the scientific and medical opportunities. Society has great diversity with respect to religious beliefs, concepts of individual rights, tolerance for uncertainty and risk, and boundaries for how scientific interventions should be used to alter the outcome of disease. In the United States, the federal government has authorized research using existing human ES cell lines but still restricts the use of federal funds for developing new human ES cell lines. Ongoing studies of existing lines have indicated that they develop abnormalities with time in culture and that they may be contaminated with mouse proteins. These findings highlight the need to develop new human ES cell lines. The development of iPS cell technology may lessen the need for deriving new ES cell lines, but it is still not clear whether the differences in gene expression by ES and iPS cells are important for potential clinical use.

In considering ethical issues associated with the use of stem cells, it is helpful to draw from experience with other scientific advances, such as organ transplantation, recombinant DNA technology, implantation of mechanical devices, neuroscience and cognitive research, in vitro fertilization, and prenatal genetic testing. These and other precedents have pointed to the importance of understanding and testing fundamental biology in the laboratory setting and in animal models before applying new techniques in carefully controlled clinical trials. When these trials occur, they must include full informed consent and careful oversight by external review groups.

Ultimately, there will be medical interventions that are scientifically feasible but ethically or socially unacceptable to some members of a society. Stem cell research raises fundamentally difficult questions about the definition of human life, and it has raised deep fears about the ability to balance issues of justice and safety with the needs of critically ill patients. Health care providers and experts with backgrounds in ethics, law, and sociology must help guard against the premature or inappropriate application of stem cell therapies and the inappropriate involvement of vulnerable population groups. However, these therapies offer important new strategies for the treatment of otherwise irreversible disorders. An open dialogue among the scientific community, physicians, patients and their advocates, lawmakers, and the lay population is critically important to raise and address important ethical issues and balance the benefits and risks associated with stem cell transfer.

474 Microbial Genomics and Infectious Disease

Roby P. Bhattacharyya, Yonatan H. Grad, Deborah T. Hung

Just as microscopy opened up the worlds of microbiology by providing a tool with which to visualize microorganisms, technological advances in genomics are now providing microbiologists with powerful new methods to characterize the genetic map that underlies all microbes with unprecedented resolution, thereby illuminating their complex and dynamic interactions with each other, the environment, and human health. The field of infectious disease genomics encompasses a vast frontier of active research that is beginning to transform the clinical practice of infectious diseases. While genetics has long played a key role in elucidating the process of infection and impacting clinical infectious diseases, the ability to extend our thinking and our approaches beyond the study of single genes to an examination of the sequence, structure, and function of entire genomes is allowing us to identify new possibilities for research and opportunities to change clinical practice. From the development of diagnostics with unprecedented sensitivity, specificity, and speed to the design of novel public health interventions, technical and statistical genomic innovations are reshaping our understanding of the influence of the microbial world on human health and providing us with new tools to diagnose, track, and combat infection. In this chapter, we explore the application of genomics methods to

TABLE 474-1 Glossary of Selected Terms in Genomics

TERM	DEFINITION
Contig	A DNA sequence representing a continuous fragment of a genome, assembled from overlapping sequences; relevant for de novo assembly of sequence data that do not align to previously sequenced genomes
Genome	The entire set of heritable genetic material within an organism
Horizontal gene transfer	The transfer of genes between organisms through mechanisms other than by clonal descent, such as through transformation, conjugation, or transduction
Metagenomics	Analysis of genetic material from multiple species directly from primary samples without requiring prior culture steps
Microarray	A collection of DNA oligonucleotides ("oligos") spatially arranged on a solid surface and used to detect or quantify sequences in a sample of interest that are complementary (and therefore bind) to one or more of the arrayed oligos
Microbial genome-wide association study (GWAS)	An analytic framework to test statistical associations between microbial genotypes and phenotypes of interest, such as antibiotic resistance and virulence
Mobile genetic elements	DNA elements that can move within a genome and can be transferred between genomes through horizontal gene transfer (e.g., plasmids, bacteriophages, and transposons)
Multilocus sequence typing	A method for typing organisms based on DNA sequence fragments from a prespecified set of genes
Next-generation sequencing	High-throughput sequencing using a parallelized sequencing process that produces millions of sequences concurrently, far beyond the capacity of prior dye-terminator methods
Nucleic acid amplification test (NAAT)	A biochemical assay that evaluates for the presence of a particular string of nucleic acids through amplification by one of several methods, including polymerase and ligase chain reactions
Polymerase chain reaction (PCR)	A type of NAAT used to amplify a specific region of DNA by means of specific oligonucleotide primers and a DNA polymerase
Single-nucleotide polymorphism (SNP)	Point mutations, the number of which in different microbial isolates is a measure of their genetic distance from one another
Transcriptome	The catalog of the full set of messenger RNA (mRNA) transcripts from a cell or organism, which are typically measured by microarray or by next-generation sequencing of complementary DNA (cDNA) via a process called RNA-Seq
Whole-genome sequencing (WGS)	A process that determines the full DNA sequence of an organism's genome; has been greatly facilitated by next-generation sequencing technology

microbial pathogens and the infections they cause. We discuss innovations that are driving the development of diagnostic approaches as well as the discovery of new pathogens, providing insight into novel therapeutic approaches and paradigms, and advancing methods in infectious disease epidemiology and the study of pathogen evolution that can inform infection control measures, public health responses to outbreaks, and vaccine development. We draw on examples in current practice and from the recent scientific literature as signposts that point toward ways in which the insights from pathogen genomics may influence infectious diseases in the short and long terms. Table 474-1 provides definitions for a selection of important terms used in genomics.

MICROBIAL DIAGNOSTICS

The basic goals of a clinical microbiology laboratory are to establish the presence of a pathogen in a clinical sample, to identify the pathogen, and, when possible, to provide other information that can help guide clinical management and even affect prognosis, such as antibiotic susceptibility profiles or the presence of virulence factors. To date, clinical microbiology laboratories have largely approached these goals phenotypically by growth-based assays and biochemical testing. Bacteria, for instance, are algorithmically grouped into species by their characteristic microscopic appearance, nutrient requirements for growth, and ability to catalyze certain reactions. Antibiotic susceptibility is determined in most cases by assessing bacterial growth in the presence of antibiotic.

With the sequencing revolution paving the way to easy access of complete pathogen genomes (Fig. 474-1), we are now able to more systematically understand the genetic basis for these observable phenotypes. Compared with traditional growth-based methods for bacterial diagnostics that dominate the clinical microbiology laboratory, nucleic acid–based diagnostics promise improved speed, sensitivity, specificity, and breadth of information. Bridging clinical and research laboratories, adaptations of genomic technologies have begun to deliver on this promise (Table 474-2).

HISTORICAL LIMITATIONS AND PROGRESS THROUGH GENETIC APPROACHES

The molecular diagnostics revolution in the clinical microbiology laboratory is well under way, born of necessity in the effort to identify microbes that are refractory to traditional culture methods. Historically, diagnosis of many so-called unculturable pathogens has relied largely on serology and antigen detection. However, these methods provide only limited clinical information because of their suboptimal sensitivity and specificity as well as the long delays that diminish their utility for real-time patient management. Newer tests to detect pathogens, based on nucleic acid content, have already offered improvements in the select cases in which they have been applied.

Unlike direct pathogen detection, serologic diagnosis—measurement of the host's response to pathogen exposure—can typically be made only in retrospect, requiring both acute- and convalescent-phase serum samples. For chronic infections, distinguishing active from latent infection or identifying repeat exposure from serology alone can be difficult or impossible, depending on the syndrome. In addition, serologic diagnosis is variably sensitive, depending on the organism and the patient's immune status. For instance, tuberculosis is notoriously difficult to identify by serologic methods; tuberculin skin testing using purified protein derivative (PPD) is especially insensitive in active disease and possibly cross-reactive with vaccines or other mycobacteria. Even the newer interferon γ release assays (IGRAs), which measure cytokine release from T lymphocytes in response to *Mycobacterium tuberculosis*–specific antigens in vitro, have limited sensitivity in immunodeficient hosts. Neither PPD testing nor IGRAs can distinguish latent from active infection. Serologic Lyme disease diagnostics suffer similar limitations: in patients from endemic regions, the presence of IgG antibodies to *Borrelia burgdorferi* may reflect prior exposure rather than active disease, while IgM antibodies are imperfectly sensitive and specific (50% and 80%, respectively, in early disease). The complicated nature of these tests, particularly in view of the nonspecific symptoms that may accompany Lyme disease, has had substantial implications for public

TABLE 474-2 Selected Clinical Applications of Infectious Disease Genomics

APPLICATION	TECHNOLOGY	NOTES/EXAMPLES
Organism Identification		
Viral detection	PCR	Identification of HIV, HBV, HCV, respiratory viruses including influenza, and others for diagnosis and response to therapy
TB detection	PCR	Amplification of the *rpoB* gene for species-specific identification of *Mycobacterium tuberculosis*
Pathogen detection	PCR, NAAT	Multiplexed identification of dozens of viruses, bacteria, yeasts, and parasites from a variety of clinical specimens
Bacterial detection	16S ribosomal gene sequencing	Targeted amplification and sequencing of regions of the 16S rRNA gene for identification of suspected bacterial infections undiagnosed by conventional methods
Pathogen Discovery		
Bacterial pathogens	Sequencing, metagenomic assembly	Unbiased "shotgun" sequencing of isolated nucleic acid from patient samples to identify associated pathogens; proofs-of-concept: new *Bradyrhizobium* species associated with cord colitis; *Escherichia coli* 0104:H4 from 2011 diarrheal outbreak in Germany; *Leptospira* species from one patient's cerebrospinal fluid; research use only at this time
Viral pathogens	Microarray, sequencing	Hybridization of clinical samples to microarrays from phylogenetically diverse known viruses identified the SARS coronavirus and others. Direct sequencing has identified West Nile virus and the MERS coronavirus, among others. Use is primarily in research.
Antibiotic Resistance		
MRSA detection	PCR	Detection of the *mecA* gene, the genotypic cause of methicillin resistance in *Staphylococcus aureus*
VRE detection	PCR	Detection of the *vanA* or *vanB* gene, the main genotypic causes of vancomycin resistance in *Enterococcus*
MDR-TB detection	PCR, NAAT	Detection of polymorphisms in the *rpoB* gene from *M. tuberculosis*, which account for 95% of rifampin resistance. Other probes available for *inhA* and *katG* genes can detect up to 85% of isoniazid resistance.
Carbapenemase detection	PCR	Detection of genes encoding one of several types of enzymes (KPC, NDM, OXA-48, IMP-1, VIM) that hydrolyze carbapenems, accounting for much but not all carbapenemase resistance in Enterobacteriaceae
HIV resistance detection	Targeted sequencing	Targeted sequencing of specific genes with known resistance-conferring mutations; now the standard of care prior to initial therapy in the United States and Europe
Epidemiology		
Outbreak and epidemic tracking	Sequencing	Application to tracking outbreaks and epidemics on local and international scales, including spread of carbapenemase-producing *Klebsiella*, *S. aureus*, *M. tuberculosis*, *E. coli*, *Vibrio cholerae*, Ebola virus, Zika virus, and influenza virus
Evolution and spread of pathogens	Sequencing	Sequencing collections of pathogens to shed light on pathogen dissemination, virulence factors, and antibiotic resistance determinants; innumerable examples, including *V. cholerae*, influenza virus, Ebola virus, and Zika virus

Abbreviations: HBV, hepatitis B virus; HCV, hepatitis C virus; MDR, multidrug-resistant; MERS, Middle East respiratory syndrome; MRSA, methicillin-resistant *S. aureus*; NAAT, nucleic acid amplification test; PCR, polymerase chain reaction; SARS, severe acute respiratory syndrome; TB, tuberculosis; VRE, vancomycin-resistant enterococci.

perception of Lyme disease and antibiotic misuse in endemic areas. Similarly, syphilis, a chronic infection caused by *Treponema pallidum*, is notoriously difficult to stage by serology alone, requiring multiple different nontreponemal and treponemal tests (e.g., rapid protein reagin and fluorescent treponemal antibody, respectively) in conjunction with clinical suspicion. Complementing serology, antigen detection can improve sensitivity and specificity in select cases, but has been validated only for a limited set of infections. Typically, structural elements of pathogens are detected, including components of viral envelopes (e.g., hepatitis B surface antigen, HIV p24 antigen), cell surface markers in certain bacteria (e.g., *Streptococcus pneumoniae*, *Legionella pneumophila* serotype 1) or fungi (e.g., *Cryptococcus*, *Histoplasma*), and less specific fungal cell-wall components such as galactomannan and β-glucan (e.g., *Aspergillus* and other dimorphic fungi).

Given the impracticality of culture and the lack of sensitivity or sufficient clinical information afforded by serologic and antigenic methods, the push toward nucleic acid–based diagnostics originated in pursuit of viruses and fastidious bacteria, becoming part of the standard of care for select organisms in U.S. hospitals. Such tests, including polymerase chain reaction (PCR) and other nucleic acid amplification tests (NAATs), are now widely used for many viral infections, both chronic (e.g., HIV infection, hepatitis C) and acute (e.g., influenza). NAATs provide essential information about both the initial diagnosis and the response to therapy and in some cases genotypically predict drug resistance. Indeed, progression from antigen detection to PCR transformed our understanding of the natural course of HIV infection, with profound implications for treatment **(Fig. 474-2*A*)**. In the early years of the AIDS pandemic, p24 antigenemia was detected in acute HIV infection but then disappeared for years before emerging again with progression to AIDS **(Fig. 474-2*B*)**. Without a marker demonstrating viremia, the role of treatment during HIV infection prior to the development of clinical AIDS was uncertain, and assessing treatment efficacy was challenging. With the emergence of PCR as a progressively more sensitive test (now able to detect as few as 20 copies of virus per milliliter of blood), viremia was recognized as a near-universal feature of HIV infection. Given the challenges of phenotypic assays, genotypic antiviral resistance testing was also adopted early for HIV and is now the standard of care before the initiation of therapy in developed countries. These developments have been transformative in guiding therapy in early disease and, together with the development of less toxic therapies, have helped to shape policy that is moving toward ever-earlier introduction of antiretroviral therapy in HIV infection.

As they are for viral testing, nucleic acid–based tests have become the diagnostic tests of choice for fastidious bacteria, including the common sexually transmitted bacterial pathogens *Neisseria gonorrhoeae* and *Chlamydia trachomatis* as well as the tick-borne *Ehrlichia chaffeensis* and *Anaplasma phagocytophilum*. More recently, nucleic acid amplification–based detection has offered improved sensitivity for diagnosis of the important nosocomial pathogen *Clostridium difficile*, and NAATs have provided clinically relevant information on the presence of cytotoxins A and B as well as molecular markers of hypervirulence, such as the North American pulsotype 1 (NAP1) strain that is enriched in severe illness. The importance of genomics in selecting loci for diagnostic assays and in monitoring test sensitivity was highlighted by the emergence in

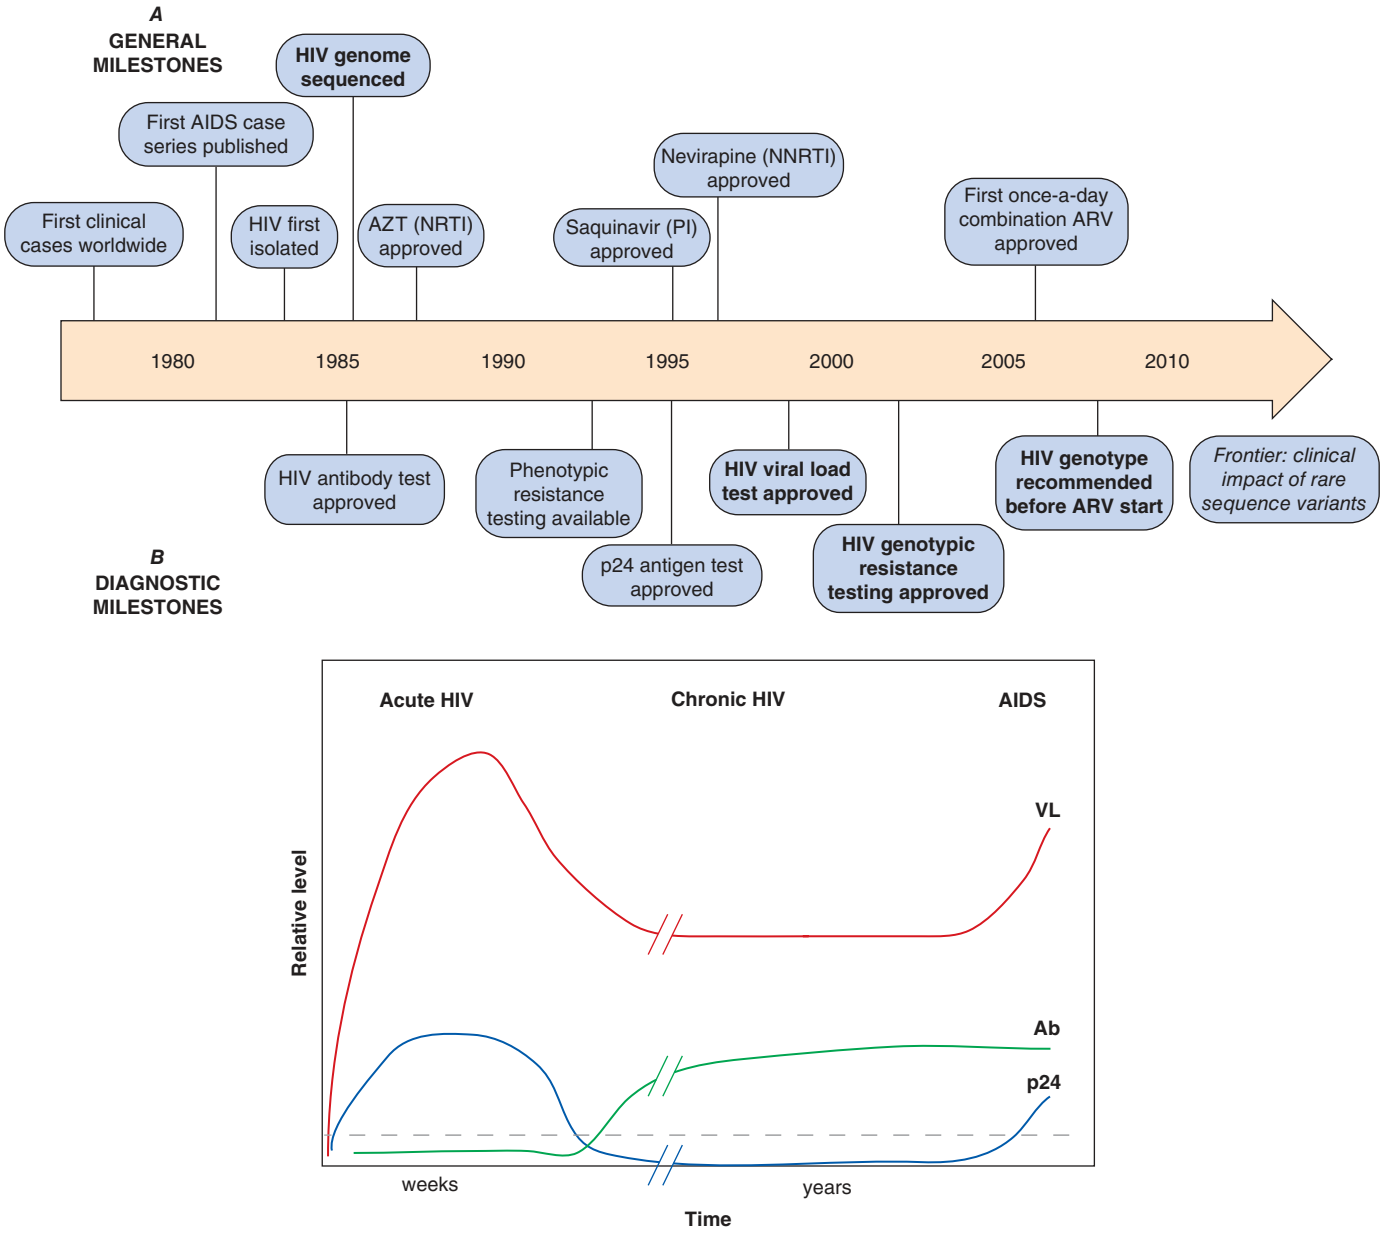

FIGURE 474-2 ***A.*** Timeline of select milestones in HIV management. Genomic advances are shown in bold type. The approvals and recommendations indicated apply to the United States. ARV, antiretroviral; AZT, zidovudine; NRTI, nucleoside reverse transcriptase (RT) inhibitor; NNRTI, nonnucleoside RT inhibitor; PI, protease inhibitor. ***B.*** Viral dynamics in the natural history of HIV infection. Three diagnostic markers are shown: HIV antibody (Ab), p24 antigen (p24), and viral load (VL). *Dashed gray line* represents limit of detection. *(Adapted from data in HH Fiebig et al: Dynamics of HIV viremia and antibody seroconversion in plasma donors: Implications for diagnosis and staging of primary HIV infection. AIDS 17:1871, 2003.)*

Sweden of a newly recognized variant of *C. trachomatis* with a deletion that includes the gene targeted by a set of commercial NAATs. By evading detection through this deletion (and thus avoiding treatment), this strain came to be highly prevalent in some areas of Sweden. While nucleic acid–based tests remain the diagnostic approach of choice for fastidious bacteria, this example serves as a reminder of the need for careful development and ongoing monitoring of molecular diagnostics.

In contrast, for typical bacterial pathogens for which culture methods are well established, growth-based assays followed by biochemical tests still dominate in the clinical laboratory. Informed by decades of clinical microbiology, these tests have served clinicians well, yet the limitations of growth-based tests—in particular, the delays associated with waiting for growth—have left opportunities for improvements. Driven by this need, mass spectrometry–based assays are already being adopted for highly accurate organism identification within a few hours of a positive blood culture. Looking ahead, molecular diagnostics, greatly informed by the vast quantity of microbial genome sequences generated in recent years, offers a way forward. First, sequencing studies can readily identify key genes (or noncoding nucleic acids) that can be developed into targets for clinical assays using PCR or hybridization assay platforms. Second, sequencing itself may eventually become cheap and rapid enough to be performed routinely on clinical specimens, with consequent unbiased detection of pathogens.

One of the biggest drivers for the implementation of novel molecular technologies in the diagnosis of infectious diseases is the desire for more rapid—or even real-time—pathogen identification, ideally with antibiotic susceptibility information on those microbes for which resistance to the current anti-infective armamentarium is of concern. Such real-time tests have the potential to transform infectious disease management, impacting antibiotic stewardship in the outpatient setting, mortality risk in the critically ill (i.e., patients in whom early administration of effective antibiotics is the most significant factor in decreasing mortality risk), hospital admission, and length of hospital stay; the extent of this impact will depend on the economic forces that will help define the breadth of their deployment. On the public health level, such tests will likely play a role in improving antibiotic stewardship,

thereby influencing the rise of antibiotic resistance and enabling surveillance of outbreaks by local, national, and international networks. In the United States and the United Kingdom, for example, public health agencies have shifted from pulsed-field gel electrophoresis to genome sequencing to track food-borne pathogens and identify outbreaks; in addition, these countries are rapidly expanding the routine use of genomics in identifying and characterizing other pathogens, from mycobacteria (both *M. tuberculosis* and nontuberculous mycobacteria) to *N. gonorrhoeae*. Further, international efforts to track the spread of viral diseases, including recent work on Ebola and Zika outbreaks and ongoing work on seasonal influenza, offer opportunities for improving interventions, surveillance, and prevention efforts, ranging from more accurate selection of the influenza virus strains to include in seasonal vaccine development to improved design of trials to evaluate novel vaccines and therapies.

Technological innovations are lowering several critical barriers to the widespread adoption of genomics and other molecular methods. Specifically, for clinical sequencing: (1) the cost and speed of sequencing and analysis methods continue to fall precipitously; (2) automation and miniaturization of the preparation of a sample for sequencing promise to reduce cost and minimize the expertise needed; and (3) direct sequencing technologies that eliminate the complex molecular biology required to prepare clinical samples for sequencing are improving in accuracy and robustness. Further barriers exist, including the need for standardized pipelines to process data and present clinicians with easily interpretable and readily actionable results. However, as these advances give rise to rapid, accurate diagnostic tests, the ultimate goal is to inform a clinician in real time whether antibiotics are indicated and, if so, which will be effective. Real-time diagnostics will allow more efficient deployment of our precious antibiotic arsenal, thus improving both societal and patient-specific outcomes in much the same way that a rapid, sensitive troponin assay has transformed bedside management of chest pain.

ORGANISM IDENTIFICATION

In order to adapt nucleic acid detection to diagnostic tests and thus to identify pathogens on a wide scale, sequences must be found that are conserved enough within a species to identify the diversity of strains that may be encountered in various clinical settings, but divergent enough to distinguish one species from another. Until recently, this problem has been solved for bacteria by targeting the element of a bacterial genome that is most highly conserved within a species, the 16S ribosomal RNA (rRNA) subunit. This method has now been used to confirm *Mycobacterium chimaera* infections in several patients after cardiothoracic surgery, leading ultimately to recognition of a widespread outbreak. At present, 16S PCR amplification from tissue specimens can be performed by specialty laboratories, though its sensitivity and clinical utility to date have remained somewhat limited, in part because of the rarity of pathogen nucleic acid in the sampled tissue, which necessitates reliable, sensitive nucleic acid amplification. As such barriers are reduced through technological advances and as the causes of culture-negative infection are clarified (perhaps in part through sequencing efforts), these tests may become both more accessible and more helpful.

With the wealth of sequencing data now available, other regions beyond 16S rRNA can be targeted for bacterial species identification. These other genomic loci can provide additional information about a clinical isolate that is relevant to patient management. For instance, detection of the presence, or potentially even the expression, of toxin genes such as *C. difficile* toxins A and B or Shiga toxin may provide clinicians with additional information that will help distinguish commensals or colonizing bacteria from pathogens and thus aid in prognostication and management as well as in diagnosis.

While amplification tests such as PCR exemplify one approach to nucleic acid detection, other approaches exist, including detection by hybridization. Although not currently used in the clinical realm, techniques for detection and identification of pathogens by hybridization to microarrays are being developed for other purposes. Of note, these different detection techniques require different degrees of conservation. Highly sensitive amplification methods require a high degree of sequence identity between PCR primer pairs and their short, specific target sequences; even a single base-pair mismatch (particularly near the 3′ end of the primer) may interfere with detection. In contrast, hybridization-based tests are more tolerant of mismatch and thus can be used to detect important regions that may be less precisely conserved within a species, thus potentially allowing detection of clinical isolates from a given species with greater diversity between isolates. Such assays take advantage of the predictable binding interactions of nucleic acids. The applicability of hybridization-based methods toward either DNA or RNA opens up the possibility of expression profiling, which can uncover phenotypic information from nucleic acid content.

Both PCR and hybridization methods target specific, known organisms. At the other extreme, as sequencing costs decline, metagenomic sequencing from patient samples is increasingly feasible. This shotgun sequencing approach is unbiased—i.e., is able to detect any microbial sequence, however divergent or unexpected. In one recent example, a clinical sample of cerebrospinal fluid from an immunocompromised patient with signs and symptoms of chronic meningitis was found through metagenomic sequencing and analysis to contain small amounts of *Leptospira* DNA. In light of this information, retrospective PCR testing confirmed the diagnosis of neuroleptospirosis, which had been missed prior to the sequencing result. The patient was treated with penicillin G and clinically recovered. Increasingly, efforts are under way to bring whole-genome sequencing to other clinical samples, including sputum and blood, in order to more readily identify pathogens. This new approach brings its own set of challenges, however, including the need to recognize pathogenic sequences against a background of expected host and commensal sequences, and to distinguish true pathogens from either colonizers or laboratory contaminants. The burgeoning field of microbiome research is driving technology development for sequencing and analyzing complex microbial communities. Lessons from this field will inform diagnostic efforts.

PATHOGEN DISCOVERY

In addition to clinical diagnostic applications, novel genomic technologies, including whole-genome sequencing, are being applied to clinical research specimens with a goal of identifying new pathogens in a variety of circumstances. The tremendous sensitivity and unbiased nature of sequencing is also ideal in searching clinical samples for unknown or unsuspected pathogens.

Causal inference in infectious diseases has progressed since the time of Koch, whose historical postulates provided a rigorous framework for attributing a disease to a microorganism. To modernize Koch's postulates: an organism, whether it can be cultured or not, should induce disease upon introduction into a healthy host if it is to be implicated as a causative pathogen. Current sequencing technologies are ideal for advancing this modern version of Koch's postulates because they can identify candidate causal pathogens with unprecedented sensitivity and in an unbiased way, unencumbered by limitations such as culturability. Yet, as direct sequencing on primary patient samples greatly expands our ability to recognize associations between microbes and disease states, critical thinking and experimentation will remain vital in establishing causality.

Virus discovery in particular has been greatly facilitated by new nucleic acid technology. These frontiers were first notably explored with high-density microarrays containing spatially arrayed sequences from a phylogenetically diverse collection of viruses. Despite bias toward those with homology to known viruses, novel viruses in clinical samples were successfully identified on the basis of their ability to hybridize to these prespecified sequences. This methodology famously contributed to identification of the coronavirus causing severe acute respiratory syndrome (SARS). Once discovered, the SARS coronavirus was rapidly sequenced: the full genome was assembled in April 2003, <6 months after recognition of the first case. This accomplishment illustrates the advancing power and speed of new diagnostic technologies.

With the advent of next-generation sequencing, unbiased pathogen discovery is now possible through a process known as *metagenomic assembly* **(Fig. 474-3)**. Sequences of random nucleotide fragments can

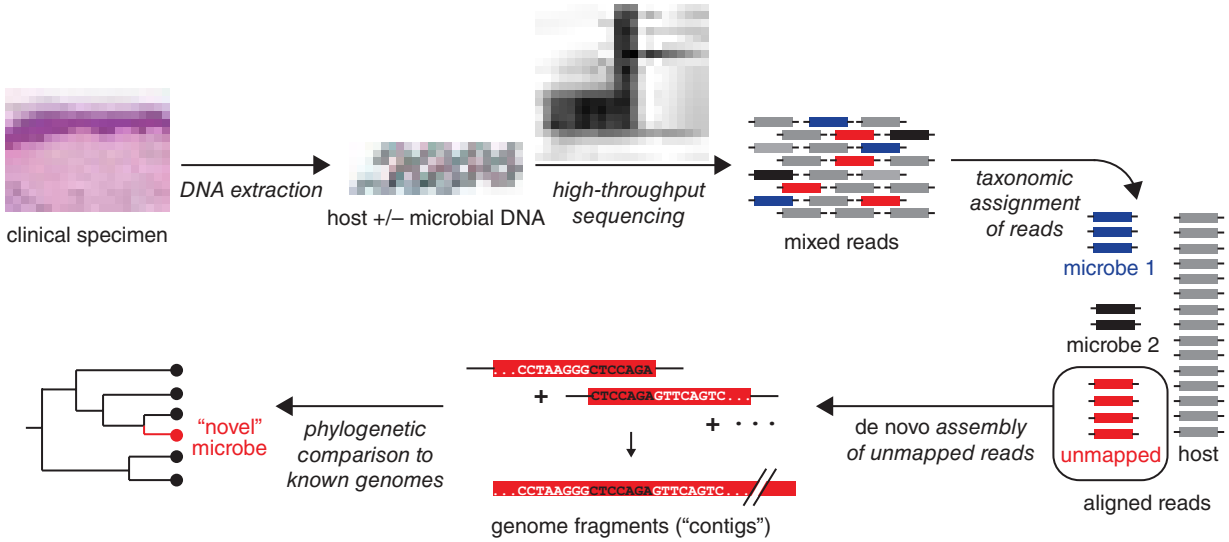

FIGURE 474-3 Workflow of metagenomic assembly for pathogen discovery. DNA is isolated from a specimen of interest (e.g., tissue, body fluid) containing a mixture of host DNA and nucleic acids from coexisting microbes, either commensal or pathogenic. All DNA (and RNA, if a reverse transcription step is added) is then sequenced, yielding a mixture of DNA sequence fragments ("reads") from the organisms present. Except for reads that do not align ("map") to any known sequence, these reads are aligned to existing reference genomes for the host or any known microbes. The unmapped reads are computationally assembled de novo into the largest contiguous stretches of DNA possible ("contigs"), representing fragments of previously unsequenced genomes. These genome fragments (contigs) are then mapped onto a phylogenetic tree based on their sequence. Some may represent known but as-yet-unsequenced organisms, while others will represent novel species. *(Figure prepared with valuable input from Dr. Ami S. Bhatt, personal communication.)*

be generated from clinical specimens with no a priori knowledge of pathogen identity through a process called *shotgun sequencing*. This collection of sequences can then be computationally aligned to host (i.e., human) sequences, with aligned sequences removed and remaining sequences compared with other known genomes to detect the presence of known microorganisms. Sequence fragments that remain unaligned suggest the presence of an additional organism that cannot be matched to a known, characterized genome; these reads can be assembled into contiguous nucleic acid stretches that can be compared with known sequences to construct the genome of a potentially novel organism. Assembled genomes (or parts of genomes) can then be compared with known genomes to infer the phylogeny of new organisms and identify related classes or traits. Thus, not only can this process identify unanticipated pathogens; it can even identify undiscovered organisms. Some early applications of sequencing on clinical samples have centered around the discovery of novel viruses, including such emerging pathogens as West Nile virus, SARS coronavirus, and the Middle East respiratory syndrome coronavirus (MERS-CoV) that has caused severe respiratory illnesses in healthy adults, as well as viral causes of myriad other conditions, from tropical hemorrhagic fevers to diarrhea in newborns.

As metagenomic sequencing and assembly techniques become more robust, this technology holds great promise for identifying microorganisms that are associated with clinical conditions of unknown etiology. Conventional methods already have unexpectedly linked numerous conditions with specific agents of infection—e.g., cervical and oropharyngeal cancers with human papillomavirus (HPV), Kaposi's sarcoma with human herpesvirus 8, and certain lymphomas with Epstein-Barr virus. Recently, Zika virus, first described in the 1940s, was found to be increasing in incidence as a cause of febrile syndromes, particularly in Central and South America. A concurrent increase in the incidence of microcephaly was noted that temporally and geographically matched the Zika epidemics. Zika was suspected to be neurotropic because of a previously recognized association with Guillain-Barré syndrome, but the strongest link between Zika virus and microcephaly came when the virus itself was detected by both quantitative reverse transcription PCR (RT-qPCR) and whole-genome sequencing in postmortem fetal brain tissue from microcephalic infants. An argument for causality was built on the foundation of epidemiologic evidence and direct viral detection, both of which were built on nucleic acid detection and genome sequencing. Sequencing techniques offer unprecedented sensitivity and specificity for identifying foreign nucleic acid sequences that may suggest other such pathogen-associated conditions—from malignancies to inflammatory conditions to unexplained fevers or other clinical syndromes—associated with organisms from viruses to bacteria to parasites. Caution is needed, though: in the absence of the ability to fulfill Koch's postulates, sequence-based identification of a microbe from patient specimens is not, on its own, sufficient to identify a novel pathogen. The increasing sensitivity of these methods warrants greater rigor and care in defining what is "noise" and what represents a pathogen.

As sequencing-based discovery expands, microbes may be found to be associated with conditions not classically thought of as infectious, such as the link between maternal Zika virus infection and fetal microcephaly. Studies of bowel flora in laboratory animals and even humans already suggest correlations between microbe composition and various aspects of metabolic and cardiovascular health. Improved methods for pathogen detection will continue to uncover unexpected correlations between microbes and disease states, but the mere presence of a microbe does not establish causality. Fortunately, once the relatively laborious and computationally intensive metagenomic sequencing and assembly efforts have identified a pathogen, further detection can more easily be undertaken with targeted methods such as PCR or hybridization, which may be more scalable and amenable to in situ confirmation. This capacity should facilitate the additional careful investigation that will be required to progress beyond correlation and to draw causal inference.

ANTIBIOTIC RESISTANCE

At present, antibiotic resistance in bacteria and fungi is conventionally determined by isolating a single colony from a cultured clinical specimen and testing its growth in the presence of drug. The requirement for multiple growth steps in these conventional assays has several consequences. First, only culturable pathogens can be readily processed. Second, this process requires considerable infrastructure to support the sterile environment needed for culture-based testing of diverse organisms. Finally, and perhaps most significantly, even the fastest-growing organisms require 1–2 days of processing for identification and 2–3 days for determination of susceptibilities. Some slow-growing organisms take even longer; for instance, weeks must pass before drug-resistant *M. tuberculosis* can be identified by growth phenotype. Given the clinical imperative in serious illness to begin effective therapy early, this inherent delay in susceptibility determination has obvious

implications for empirical antibiotic use: broad-spectrum antibiotics often must be chosen up front in situations where it is later shown that preferred narrower-spectrum drugs would have been effective or even that no antibiotics were appropriate (i.e., in viral infections). Even with this strategy, as resistant organisms become more common, the empirical choice can be incorrect, often with devastating consequences. Real-time identification of the infecting organism and information on its susceptibility profile would guide initial therapy and support judicious antibiotic use, ideally improving patient outcomes while aiding in the ever-escalating fight against antibiotic resistance by reserving the use of broad-spectrum agents for cases in which they are truly needed.

Molecular diagnostics and sequencing offer a way to accelerate detection of a pathogen's antibiotic susceptibility profile. If a genotype that confers resistance can be identified, this genotype can be targeted for molecular detection. In infectious disease, this approach has most convincingly come to fruition for HIV (Fig. 474-2*A*). (In a conceptually parallel application of genomic analysis, molecular detection of certain resistance determinants in cancers informs selection of targeted chemotherapy.) Extensive sequencing of HIV strains and correlations drawn between viral genotypes and phenotypic resistance have delineated the majority of mutations in key HIV genes, such as reverse transcriptase, protease, and integrase, that confer resistance to the antiretroviral agents that target these proteins. For instance, the single amino acid substitution K103N in the HIV reverse transcriptase gene predicts resistance to the first-line nonnucleoside reverse transcriptase inhibitor efavirenz, and its detection informs a clinician to choose a different agent. The effects of these common mutations on HIV susceptibility to various drugs—as well as on viral fitness—are curated in publicly available databases. Thus, genotypes are now routinely used to predict drug resistance in HIV, as phenotypic resistance assays are far more cumbersome than targeted sequencing. Indeed, the current recommendation in the United States is to sequence virus from a patient's blood before initiating antiretroviral therapy, which is then tailored to the predicted resistance phenotype. As new targeted therapies are introduced, this targeted sequencing–based approach to drug resistance will likely prove important in other viral infections, such as hepatitis C.

The challenge of predicting drug susceptibility from genotype is more daunting for bacteria than for HIV, yet considerable progress has been made toward sequencing-based determination of bacterial antibiotic susceptibility. Bacteria have far more complex genomes than viruses, with thousands of genes on their chromosomes (many of which can functionally interact in ways that escape a priori prediction) and the capacity to acquire many more through horizontal gene transfer of plasmids and mobile genetic elements within and between species. Thus, the task of comprehensively defining all possible genetic resistance mechanisms is orders of magnitude more complex in bacteria than in viruses, which typically have far more limited genomes. Despite these challenges, considerable progress has been made in recent years. In select cases where biological factors appear to have constrained the genotypic basis for resistance to a small, well-defined set of mutations, genotypic assays for antibiotic resistance are already being introduced into clinical practice. One important example is the detection of methicillin-resistant *Staphylococcus aureus* (MRSA). *S. aureus* is one of the most common and serious bacterial pathogens of humans, particularly in health care settings. Resistance to methicillin, the most effective class of antistaphylococcal antibiotics, has become very common, even in community-acquired strains. Vancomycin—the alternative drug to methicillin—is effective against MRSA but is measurably inferior to methicillin against methicillin-susceptible *S. aureus* (MSSA). Analysis of clinical MRSA isolates has demonstrated that the molecular basis for resistance to methicillin in essentially all cases stems from the expression of an alternative penicillin-binding protein (PBP2A) encoded by the gene *mecA*, which is found within a transferable genetic element called *mec*. This mobile cassette has spread rapidly through the *S. aureus* population via horizontal gene transfer and selection from widespread antibiotic use. Because methicillin resistance is essentially always due to the presence of the *mec* cassette, MRSA is particularly amenable to molecular detection. In recent years, a PCR test for the *mec* cassette, which saves hours to days compared with standard culture-based methods, has been approved by the U.S. Food and Drug Administration (FDA). Similar to MRSA, vancomycin-resistant enterococci (VRE) harbor one of a limited number of *van* genes found to be responsible for resistance to this important antibiotic, which occurs through alteration of the mechanism for cell wall cross-linking that vancomycin inhibits. Detection of one of these genes by PCR indicates resistance. More recently, identification of carbapenemase-encoding plasmids responsible for a significant fraction of carbapenem resistance (though not all instances) has led to multiplexed PCR assays to detect this important resistance element to this crucial antibiotic class. Finally, a PCR assay targeting the highly conserved RNA polymerase gene serves not only to detect *M. tuberculosis* directly in sputum samples but also to detect resistance to rifampin, since the determinants of resistance to this RNA polymerase inhibitor map almost exclusively to a short region of this gene. Since rifampin resistance is epidemiologically associated with, though not causal for, multidrug resistance, this assay identifies strains at high risk for multidrug resistance, enhancing its value.

Although identification and rapid detection of monogenic resistance determinants have improved, bacteria have tended to evolve multiple, diverse resistance mechanisms to most antibiotics; therefore, these tasks often require probing for and integration of multiple genetic lesions, targets, or mechanisms. For instance, at least five distinct modes of resistance to fluoroquinolones are known: reduced import, increased efflux, target site mutation, drug modification, and shielding of the target sites by expression of another protein. These mechanisms are typically present in combination in clinically resistant isolates; thus the problem of detecting genetic resistance is often a combinatorial one. In another clinically important example, while carbapenem resistance in Enterobacteriaceae is often explained by the presence of carbapenemases, resistance may also develop when other, less broad-spectrum β-lactamases are found in combination with porin mutations or efflux pumps. Thus, while multiplexed PCR assays for the most common carbapenemases (e.g., those encoded by the KPC, NDM, OXA-48, IMP-1, and VIM genes) have become a valuable tool for rapid identification of the subset of carbapenem-resistant Enterobacteriaceae in which resistance is caused by carbapenemases, their sensitivity is limited by their inability to detect other mechanisms of carbapenem resistance. To further complicate genetic prediction, changes in gene expression (which may be detectable through mutations in promoter regions or regulatory genes without coding mutations in known resistance determinants) and even gene copy number (which may occur without changes in primary sequence) of resistance determinants play critical roles in some cases of genetic resistance. Thus, while predicting resistance when determinants are found is rapidly becoming feasible, the more clinically relevant task of predicting *susceptibility* when no known resistance determinants are found remains more difficult.

To build on early successes with the goal of advancing beyond binary detection of monogenic resistance determinants, the ultimate frontier for genetic prediction of bacterial antibiotic resistance lies in more comprehensive prediction of a resistance phenotype from sequence information—a task similar to HIV resistance prediction. Yet there is no comprehensive compendium of genetic elements conferring resistance and their pairwise and higher-order interactions with each other and with the genetic background of bacterial pathogens. Nonviral genomes are much larger than viral ones, and their abundance and diversity are such that thousands of genetic differences often exist between clinical isolates of the same species, of which perhaps only one or a few may contribute to resistance. In addition, new mechanisms may emerge in the face of antibiotic deployment or with the release of new drugs, and genetic prediction of resistance will inevitably lag behind the emergence of unforeseen mechanisms. While confident prediction of bacterial antibiotic resistance from sequencing determinants may therefore seem daunting, the vast expansion of microbial sequencing capacity (Fig. 474-1), combined with analytic methods such as microbial genome-wide association studies and machine learning algorithms, offers powerful analytical approaches to this "needle in a haystack" problem and has permitted remarkable advances in the

predictive power of sequence determinants to date. Particularly in *M. tuberculosis*, where horizontal gene transfer is minimal and the pathogen is essentially restricted to human hosts, a remarkably wide array of phenotypic resistance can be explained by known genetic determinants. Even in more highly variable pathogens, with sequencing of sufficient numbers of susceptible and resistant pathogens, sequence-based prediction methods are improving in predictive accuracy, at least within the geographic region from which the test samples have been sequenced.

It is important to note that genotype-based analytical methods largely identify correlates, not necessarily surrogates or determinants, of resistance. In HIV diagnostics, surrogates (i.e., causal determinants of resistance) were found to be more reliable predictors than mere correlates in expanding sequencing-based resistance prediction to the general population. Without a mechanistic understanding of genetic resistance, a correlative relationship may be lineage-specific and less generalizable. Especially with multiple possible mechanisms of resistance to a given antibiotic and ongoing evolutionary pressure resulting in the development and acquisition of new modes of resistance, a genotypic approach to diagnosing antibiotic resistance is likely to remain challenging and to require ongoing vigilance in constantly correlating genotypic with more traditional phenotypic methods. An important corollary benefit of a genomic approach to resistance prediction, anchored in phenotypic validation, could be the systematic identification of outliers with unexplained resistance. These strains can form the basis for understanding newly emerging resistance mechanisms, which can in turn inform new drug development endeavors. Understanding resistance mechanisms may also help direct infection control efforts. For instance, the first identification of the *mcr-1* (mobilized colistin resistance) gene on a plasmid, together with other antibiotic resistance determinants, heightened concern about colistin-resistant Enterobacteriaceae identified first in China and later elsewhere because it implied rapid transmissibility of multidrug resistance. Early recognition of these potentially dangerous strains elucidated the immediate need for strict containment protocols.

In parallel with advancing sequencing technologies, progress in computational techniques, bioinformatics and statistics, and data storage as well as experimental confirmatory testing of hypotheses will be needed to advance toward the ambitious goal of a comprehensive compendium of global antibiotic resistance determinants. Open sharing and careful curation of new sequence information will be of paramount importance, as will iterative or even continuous comparison of predictions with ongoing phenotypic testing in order to assess performance and allow prediction algorithms to keep up with newly evolving or emerging resistance mechanisms.

We continuously observe the accumulation of new or unanticipated modes of resistance from ongoing evolutionary pressure caused by the widespread clinical use of antibiotics. Even with MRSA, perhaps the best-studied case of antibiotic resistance and a model of relative simplicity with a single known monogenic resistance determinant (*mecA*), a genotype-based approach to resistance detection proved imperfect. One limitation was a recall of the initial commercial genotypic resistance assay that was deployed for the identification of MRSA. A clinical isolate of *S. aureus* that emerged in Belgium expressed a variant of the *mec* cassette not detected by the assay's PCR primers. New primers were added to detect this new variant, and the assay was re-approved for use. This example illustrates the need for ongoing monitoring of any genotypic resistance assay. A second limitation is that a contradiction can occur between genotypic and phenotypic evidence for resistance. Up to 5% of MSSA strains have been reported to carry a copy of the *mecA* gene that is either nonfunctional or not expressed. Thus, the erroneous identification of these strains as MRSA by genotypic detection would lead to administration of the inferior antibiotic vancomycin rather than the preferred β-lactam therapy.

These examples illustrate one of the prime challenges of moving beyond growth-based assays: genotype is merely a proxy for the resistance phenotype that directly informs patient care. Alternative approaches currently under development attempt to circumvent the limitations of genotypic resistance testing by returning to phenotypic assays, albeit more rapid ones. One such approach is informed by genomic methods: transcriptional profiles serve as a rapid phenotypic signature for antibiotic response. Conceptually, since dying cells are transcriptionally distinct from cells fated to survive, susceptible bacteria enact different transcriptional profiles after antibiotic exposure than resistant ones, independent of the mechanism of resistance. These differences can be measured and, since transcription is one of the most rapid responses to cell stress (minutes to hours), can be used to determine whether cells are resistant or susceptible much more rapidly than is possible if growth in the presence of antibiotics is awaited (days). Like DNA, RNA can be readily detected through predictable rules governing base pairing via either amplification or hybridization-based methods. Changes in a carefully selected set of transcripts form an expression signature that can represent the total cellular response to antibiotic without requiring full characterization of the entire transcriptome. Preliminary proof-of-concept studies suggest that this approach may identify antibiotic susceptibility on the basis of transcriptional phenotype much more quickly than is possible with growth-based assays.

Because of its sensitivity in detecting even very rare nucleic acid fragments, sequencing provides an unprecedented depth of study into complex populations of cells and tissues. The strength of this depth and sensitivity applies not only to the detection of rare, novel pathogens in a sea of host signal, but also to the identification of heterogeneous pathogen subpopulations in a single host that may differ, for example, in drug resistance profiles or pathogenesis determinants. For instance, recent studies have highlighted the diversification of pathogens in chronic bacterial infections, such as *Pseudomonas* in the lungs of patients with cystic fibrosis or *M. tuberculosis* in disseminated infection, perhaps allowing for niche specialization within the host. Such diversification has long been recognized in chronic viral populations, as exemplified by HIV. Future studies will be needed to elucidate the clinical significance of these variable subpopulations, even as deep sequencing is now providing unprecedented levels of detail about majority and minority members of this population.

HOST-BASED DIAGNOSTICS

While pathogen-based diagnostics continue to be the mainstay for confirming infection, serologic testing and nonspecific biomarkers—such as erythrocyte sedimentation rate, C-reactive protein level, and even total white blood cell and neutrophil counts—have long been the basis of a strategy for measuring host responses to aid in the diagnosis of infection. Even recently identified host biomarkers of bacterial infection, such as procalcitonin, have fallen short in their versatility, with positive and negative predictive values that are thus far adequate for only a few narrow applications but inadequate for generalized clinical use. Here, too, the application of genomics is now being explored to improve upon this approach, given the previously described limitations of serologic testing and the lack of specificity of protein biomarkers identified to date. Rather than using antibody responses as a retrospective biomarker for infection, recent efforts have focused on transcriptomic analysis of the host response as a new direction with diagnostic implications for human disease. For instance, while pathogen-based diagnostic tests to distinguish active from latent tuberculosis infection have proven elusive, recent work shows that the transcriptional profile of circulating white blood cells exhibits a differential pattern of expression of nearly 400 transcripts that distinguish active from latent tuberculosis; this expression pattern is driven in part by changes in interferon-inducible genes in the myeloid lineage. In a validation cohort, this transcriptional signature was able to distinguish patients with active versus latent disease, to distinguish tuberculosis infection from other pulmonary inflammatory states or infections, and to track responses to treatment in as little as 2 weeks, with normalization of expression toward that of patients without active disease over 6 months of effective therapy. Such a test could play an important role not only in the management of patients but also as a marker of efficacy in clinical trials of new therapeutic agents. Similarly, considerable progress has been made toward identifying host transcriptional signatures in circulating blood cells that distinguish viral from bacterial causes

of upper respiratory infection, with better performance characteristics than current clinical parameters or available protein biomarkers. Additional host signatures have been reported that distinguish among bacterial infection, viral infection, and inflammatory states; identify Lyme disease; identify influenza; and even distinguish between gram-positive and gram-negative bacterial infections. In some cases, results have been extended to different host populations—including adults and children, and those with varying immune function—which obviously will be critical for generalizing such an approach. Thus, profiling of host transcriptional dynamics could augment the information obtained from studies of pathogens, both enhancing diagnosis and monitoring the progression of illness and the response to therapy.

In this era of genome-wide association studies and attempts to move toward personalized medicine, genomic approaches are also being applied to the identification of host genetic loci and factors that contribute to infection susceptibility. Such loci will have undergone strong selection among populations in which the disease is endemic. Through identification of the beneficial genetic alleles among individuals who survive in such settings, markers for susceptibility or resistance are being discovered; these markers can be translated to diagnostic tests to identify susceptible individuals in order to implement preventive or prophylactic interventions. Further, such studies may offer mechanistic insight into the pathogenesis of infection and inform new methods of therapeutic intervention. Such beneficial genetic associations were recognized long before the advent of genomics, as in the protective effects of the negative Duffy blood group or heterozygous hemoglobin abnormalities against *Plasmodium* infection. Genomic approaches allow more systematic and widespread application of this principle to identify not only people with increased susceptibility to prevalent diseases (e.g., HIV infection, tuberculosis, and cholera) but also host factors that contribute to and thus might predict the severity of disease.

THERAPEUTICS

Genomics has the potential to impact infectious disease therapeutics in two ways. By transforming the speed or type of diagnostic information that can be attained, it can influence therapeutic decision-making. Alternatively, by opening new avenues to a better understanding of pathogenesis, providing new ways to disrupt infection, and delineating new approaches to antibiotic discovery, it has the potential to facilitate the development of new therapeutic agents.

GENOMIC DIAGNOSTICS INFORMING THERAPEUTICS

Efforts at antibiotic discovery are declining, with few new agents in the pipeline and even fewer new drugs (in particular, few agents with new mechanisms of action) entering the market. This phenomenon is due in part to the lack of economic incentives for the private sector; however, it is also attributable in part to the enormous challenges involved in the discovery and development of antibiotics. Most recent efforts have focused on broad-spectrum antibiotics; the development of a chemical entity that works across an extremely diverse set of organisms (i.e., species more divergent from each other than a human is from an amoeba) is far more challenging than the development of an agent that is designed to target a single bacterial species. Nevertheless, the concept of narrow-spectrum antibiotics has heretofore been rejected because of the lack of early diagnostic information that would guide the selection of such agents. Thus, rapid diagnostics providing antibiotic susceptibility information that can guide antibiotic selection in real time has the potential to alter and simplify antibiotic strategies by allowing a paradigm shift away from broad-spectrum drugs and toward narrow-spectrum agents. Such a paradigm shift clearly would have additional implications for antibiotic resistance, helping to limit selective pressure applied to pathogens and commensal bacteria during therapy.

In yet another diagnostic paradigm with the potential to impact therapeutic interventions, genomics is opening new avenues to a better understanding not only of different host susceptibilities to infection but also of different host responses to therapy. For example, the role of glucocorticoids in tuberculous meningitis has long been debated. Recently, polymorphisms in the human genetic locus *LTA4H*, which encodes a leukotriene-modifying enzyme, were found to modulate the inflammatory response to tuberculosis. Patients with tuberculous meningitis who were homozygous for the proinflammatory *LTA4H* allele were most helped by adjunctive glucocorticoid treatment, while those who were homozygous for the anti-inflammatory allele were negatively affected by steroid treatment. Steroids have become part of the standard of care in tuberculous meningitis, but this study suggests that perhaps only a subset of patients benefit from this anti-inflammatory adjunct (while others may be harmed) and further suggests a genetic means of prospectively identifying this subset. Thus, genomic diagnostic tests may eventually approach the goal of personalized medicine, informing diagnosis, prognosis, and treatment decisions by revealing the pathogenic potential of the microbe and by detecting individualized host responses to both infection and therapy.

GENOMICS IN DRUG AND VACCINE DEVELOPMENT

Genomic technologies are dramatically changing research on host–pathogen interactions, with a goal of increasingly influencing the process of therapeutic discovery and development. Sequencing offers several possible avenues into antimicrobial therapeutic discovery. First, genome-scale molecular methods have paved the way for comprehensive identification of all essential genes encoded by a pathogen, thereby systematically identifying critical vulnerabilities within a pathogen that could be targeted therapeutically. Second, genome-scale methodologies offer rapid ways to address the mechanism of action of newly identified hits from compound screens. Whole-genome sequencing offers a rapid, unbiased way to detect mutations arising in resistant mutants during selection. Similarly, transcriptional profiling can provide insights into mechanisms of action of new candidate drugs. For instance, the transcriptional signature of cell wall disruptors (e.g., β-lactams) is distinct from that of DNA-damaging agents (e.g., fluoroquinolones) or protein synthesis inhibitors (e.g., aminoglycosides). Either approach can thus suggest a mechanism of action or flag compounds for prioritization because of a potentially novel activity. In an alternative genomic strategy for determining mechanisms of action, an RNA interference approach followed by targeted sequencing was used to identify genes required for antitrypanosomal drug efficacy. This approach provided new insights into the mechanism of action of drugs that have been in use for decades for human African trypanosomiasis. Third, sequencing can readily identify the most conserved regions of a pathogen's genomes and corresponding gene products; this information is invaluable in narrowing antigen candidates in vaccine development. These surface proteins can be expressed recombinantly and tested for the ability to elicit a serologic response and protective immunity. This process, termed *reverse vaccinology*, has proved particularly useful for pathogens that are difficult to culture or poorly immunogenic.

Genomics has been employed in both developing vaccines and defining their impact on microbial epidemiology and ecology. Examples include recent studies of influenza, malaria, *S. pneumoniae*, and HPV following vaccine introduction. Extensive sequencing of influenza viruses has been valuable in understanding the modest efficacy of seasonal influenza vaccination, and the combination of genomics and antigenic cartography is proving helpful in the selection of strains to include in subsequent influenza vaccines. The new RTS,S/AS01 malaria vaccine was analyzed by targeted sequencing of parasites from vaccinated and control populations during a phase 3 trial conducted at 11 sites in Africa; these analyses revealed reduced vaccine efficacy against parasites with amino acid mutations in the circumsporozoite protein targeted by the vaccine. Similarly, studies of the more established pneumococcal vaccine (the 7-valent polysaccharide conjugate vaccine, PCV-7) documented serotype replacement: strains targeted by the vaccine have dramatically decreased in prevalence following widespread vaccination campaigns. Given that specific serotypes of HPV (e.g., types 16 and 18) clearly are more strongly associated than others with carcinogenesis, HPV vaccines have capitalized on serotype replacement, targeting vaccine strains to specifically prevent infection with the more dangerous serotypes. Such a strategy, informed by pathogen genomics, aims to protect individuals and ideally to decrease the circulating burden of more virulent strains within society.

Large-scale gene content analysis from sequencing or expression profiling enables new research directions that provide novel insights into the interplay of pathogen and host during infection or colonization. One important goal of such research is to suggest new therapeutic approaches to disrupt this interaction in favor of the host. Indeed, one of the most immediate applications of next-generation sequencing technology has come from simply characterizing human pathogens and related commensal or environmental strains and then finding genomic correlates for pathogenicity. For instance, as *Escherichia coli* varies from a simple nonpathogenic, lab-adapted strain (K-12) to a Shiga toxin–producing enterohemorrhagic gastrointestinal pathogen (O157:H7), it displays up to a 25% difference in gene content, though it is classified as the same species. Similarly, some isolates of *Enterococcus*—a genus notorious for its increasing incidence of resistance to common antibiotics such as ampicillin, vancomycin, and aminoglycosides—also contain recently acquired genetic material comprising up to 25% of the genome on mobile genetic elements. This fact suggests that horizontal gene transfer plays an important role in the organisms' adaptation as nosocomial pathogens. On closer study, this genome expansion is associated with loss of regulatory elements called CRISPRs (*c*lustered, *r*egularly *i*nterspaced *s*hort *p*alindromic *r*epeats). Loss of CRISPR elements, which protect the bacterial genome from invasion by certain foreign genetic material, may thus facilitate the acquisition of antibiotic resistance–conferring genetic elements. While loss of this regulation appears to impose a competitive disadvantage in antibiotic-free environments, these drug-resistant strains thrive in the presence of even some of the best antienterococcal therapies. In addition to insights gained from genome sequencing, extension of unbiased whole-transcriptome sequencing (RNA-Seq) efforts to bacteria is beginning to identify unexpected regulatory, noncoding RNAs in many diverse species. While the functional implications of these new transcripts are as yet largely unknown, the presence of such features—conserved across many bacterial species—implies evolutionary importance and suggests areas for future study and possible new therapeutic avenues. Transcriptomic and proteomic profiling of pathogens under various conditions that mimic colonization or infection, including existence as biofilms or in polymicrobial communities, intracellular infection models, antibiotic exposure, and nutrient starvation, has begun to reveal novel biological features that may be targeted by the next generation of therapies. At the cutting edge of the host–pathogen interface, single-cell transcriptomic methodologies are rapidly increasing in feasibility and extent, revealing previously unknown heterogeneity in the potential outcomes of intracellular infection.

Thus, genomic studies are transforming our understanding of infection, offering evidence of virulence factors or toxins and providing insight into ongoing evolution of pathogenicity and drug resistance. One goal of such studies is to identify therapeutic agents that can disrupt the pathogenic process. There is currently much interest in the theoretical concept of antivirulence drugs that inhibit virulence factors rather than killing the pathogen outright as a means to intervene in infection. Further, with sequencing ever more accessible and efficient, ongoing large-scale studies have unprecedented statistical power to associate clinical outcomes with pathogen and host genotypes and thus to further reveal vulnerabilities in the infection process that can be targeted for disruption. Although this is just the beginning, such studies point to a tantalizing future in which the clinician is armed with genomic predictors of infection outcome and therapeutic response to guide clinical decision-making.

EPIDEMIOLOGY OF INFECTIOUS DISEASES

Epidemiologic studies of infectious diseases have several main goals: to identify and characterize outbreaks, to describe the pattern and dynamics of an infectious disease as it spreads through populations, and to identify interventions that can limit or reduce the burden of disease. One classic, paradigmatic example is John Snow's elucidation of the origin of the 1854 London cholera outbreak. Snow used careful geographic mapping of cases to determine that the likely source of the outbreak was contaminated water from the Broad Street pump, and, by removing the pump handle, he aborted the outbreak. Whereas that effort was undertaken without knowledge of the causative agent of cholera, advances in microbiology and genomics have expanded the purview of epidemiology to consider not just the disease but also the pathogen, its virulence factors, and the complex relationships between microbial and host populations.

Through use of genomic tools such as high-throughput sequencing, the diversity of a microbial population can be rapidly described with unprecedented resolution, with discrimination between isolates that have single-nucleotide differences across the entire genome and advancement beyond prior approaches that relied on phenotypes (such as antibiotic susceptibility profiles) or genetic markers (such as multilocus sequence typing). The development of statistical methods grounded in molecular genetics and evolutionary theory has established analytical approaches that translate descriptions of microbial population diversity and structure into descriptions of the origin and history of pathogen spread. By linking phylogenetic reconstruction with epidemiologic and demographic data, genomic epidemiology presents the opportunity to track transmission from person to person and across demographic and geographic boundaries, to infer transmission patterns of both pathogens and sequence elements that confer phenotypes of interest, and to estimate the transmission dynamics of outbreaks.

TRANSMISSION NETWORKS

Whole-genome sequencing of pathogen genomes can be used to infer transmission and identify point-source outbreaks. As reported in a seminal paper in 2010, a study of MRSA in a Thai hospital demonstrated the use of whole-genome sequencing in reconstructing the transmission of a pathogen from patient to patient by integrating the analysis of accumulation of mutations over time with the dates and hospital locations of the infected individuals. Since then, multiple instances of the use of whole-genome sequencing to define and motivate interventions aimed at interrupting transmission chains have been reported. In another MRSA outbreak in a special-care baby unit in Cambridge, United Kingdom, whole-genome sequencing extended the traditional infection control analysis, which relies on typing organisms by their antibiotic susceptibilities, to sequencing of isolates from clinical samples. This approach identified an otherwise unrecognized outbreak of a specific MRSA strain that was occurring against a background of the usual pattern of infection caused by a diverse circulating population of MRSA strains. The analysis showed evidence of transmission among mothers within the special-care baby unit and in the community and demonstrated the key role of MRSA carriage in a single health care provider in the persistence of the outbreak. In yet another example, in response to the observation of 18 cases of infection by carbapenemase-producing *Klebsiella pneumoniae* over 6 months at the National Institutes of Health Clinical Research Center, genome sequencing of the isolates was used to discriminate between the possibilities that these cases represented multiple, independent introductions into the health care system or a single introduction with subsequent transmission. On the basis of network and phylogenetic analysis of genomic and epidemiologic data, the authors reconstructed the likely relationships among the isolates from patient to patient, demonstrating that the spread of resistant *Klebsiella* infection was in fact due to nosocomial transmission of a single strain. Similar approaches have elucidated the extent to which presumed nosocomial *C. difficile*, VRE, and carbapenem-resistant Enterobacteriaceae represent within-hospital transmission rather than independent acquisitions. With these demonstrations of the potential contribution of genomics to hospital infection-control efforts, an important avenue of research seeks to develop statistical methods with which to ascertain when such tools are useful and their cost-effectiveness when compared with that of current nongenomic approaches.

The uncovering of unexpected transmission events by genomic epidemiology studies is motivating investigations into pathogen ecology and modes of transmission. For example, the rise in prevalence of infections with nontuberculous mycobacteria, including *Mycobacterium abscessus*, among patients with cystic fibrosis has led to speculation about the possible role of patient-to-patient transmission in the cystic fibrosis community; however, conventional typing

approaches have lacked the resolution to define pathogen population structure accurately, a critical component of inferring transmission. Past infection-control guidelines discounted the possibility of acquisition of nontuberculous mycobacteria in health care settings, as no strong evidence for such transmission had been described. In whole-genome sequencing studies of *M. abscessus* isolates from patients with cystic fibrosis, an analytical approach using genome sequencing, epidemiology, and Bayesian modeling revealed that, contrary to the prior belief that infections with *M. abscessus* are independently acquired, the majority of infections appear to be transmitted. Because there are often no clear epidemiologic links that place the infected patients in the same place at the same time, this finding highlights a need to explore preexisting notions of circumstances required for transmission, including the roles of fomites and aerosols, and a reconsideration of *M. abscessus* infection-control guidelines. In a clear example of the utility of whole-genome sequencing for revealing unexpected transmission networks, isolates of *M. chimaera* causing infections after cardiothoracic surgery in patients in different locations were all found to be closely related. These isolates differed from one another by at most 38 pairwise single-nucleotide polymorphisms out of >5 million bases; in contrast, they differed by >2900 single-nucleotide polymorphisms from the nonclonally related reference isolate. Although a hospital source was initially suspected when the first of these cases were identified, this whole-genome sequencing analysis strongly supported a single point-source for these geographically dispersed isolates. A subsequent investigation ultimately implicated *M. chimaera* contamination in the manufacturing chain of a temperature-control system used during cardiac bypass. Similar studies of other pathogens—particularly those that share human, other animal host, and environmental reservoirs—will continue to advance our understanding of the relative roles and prominence of sources of infection and the modes of spread through populations, thereby establishing evidence-based strategies for prevention and intervention.

As more studies aim to carefully define the origins and spread of infectious agents using the high-resolution lens of whole-genome sequencing, fundamental questions arise about the diversity of infecting and colonizing microbial populations. Traditional microbiologic methods include taking a single colony from a growth plate as representative of the population. However, the more diverse the colonizing or infecting pathogen population, the less representative these individual isolates are and the greater the possibility for introducing error into whole-genome sequencing–based methods while reconstructing transmission. Sequencing studies of multiple colonies of an *S. aureus* strain colonizing a single individual showed a "cloud" of diversity. What is the clinical significance of this diversity? What are the processes that generate and limit it? What amount of diversity is transmitted under different conditions and routes of transmission? How do the answers to these questions vary by infectious organism, type of infection, host, and response to treatment? More comprehensive descriptions of diversity, population dynamics, transmission bottlenecks, and the forces that shape and influence the growth and spread of microbial populations will be a critically important focus of future investigations.

ORIGINS AND DYNAMICS OF PATHOGEN SPREAD

In addition to reconstructing the transmission chains of local outbreaks, genomics-based epidemiologic methods reveal broad-scale geographic and temporal spread of pathogens. Three recent examples include the origins of cholera in Haiti, the history of HIV-1 group M, and the spread of Ebola in West Africa. Cholera, a dehydrating diarrheal illness caused by infection with *Vibrio cholerae*, first spread worldwide from the Indian subcontinent in the 1800s and has since caused seven pandemics; the seventh pandemic has been ongoing since the 1960s. An investigation into the geographic patterns of cholera spread in the seventh pandemic used genome sequences from a global collection of 154 *V. cholerae* strains representing isolates from 1957 to 2010. This investigation revealed that the seventh pandemic has comprised at least three overlapping waves spreading out from the Indian subcontinent **(Fig. 474-4*A*)**. Further, analysis of the genome of an isolate of *V. cholerae* from the 2010 outbreak of cholera in Haiti showed it to be more closely related to isolates from South Asia than to isolates from neighboring Latin America, supporting the hypothesis that the outbreak was derived from *V. cholerae* introduced into Haiti by human travel (likely from Nepal) rather than by environmental or more geographically proximal sources. A subsequent study that dated the time to the most recent common ancestor of a population of *V. cholerae* isolates from Haiti provided further support for a single point-source introduction from Nepal. Application of similar methods that integrate pathogen genome sequences, mutation rates, geographic locations, and phylogenetic inference to HIV-1 group M dated the origin of the virus to the 1920s and the city of Kinshasa (then called Leopoldville), the capital of the Democratic Republic of the Congo (then called the Belgian Congo). This work established an understanding of how a boom in industry and a city with extensive railroad connections provide a scaffolding along which a virus can rapidly spread geographically.

More recently, genome sequencing has proven invaluable in understanding the geographic, demographic, climatic, and administrative factors that drove, sustained, and limited the 2013–2016 Ebola outbreak that ravaged West Africa **(Fig. 474-4*B*)** as well as the factors and patterns of transmission of Zika virus in the Americas. These efforts illustrate the remarkable promise of genome sequencing in improving outbreak response strategy by elucidating previously hidden paths of disease spread and details of the forces that shape epidemics. The combination of in-the-field sequencing with portable sequencing platforms, rapid data sharing, and rapid open analysis through sites such as nextstrain.org offers a paradigm by which real-time genomic epidemiology may contribute to "weather maps," enabling prediction of epidemic patterns and thus providing guidance for public health interventions to slow or control their spread.

Increasing numbers of investigations into the spread of many pathogens are contributing to a growing atlas of maps describing routes, patterns, and tempos of microbial diversification and dissemination, not just for agents of emerging infectious diseases but for common pathogens as well. Such studies will create a vast amount of data that can be used to investigate the diversity and microbiologic links within distinct niches and the patterns of spread from one niche to another. The increasingly broad adoption of genome sequencing by health care and public health institutions will ensure that the available catalog of genome sequences and associated epidemiologic data will grow very rapidly. For example, updating from the pulsed-field gel electrophoresis techniques that have been used to define strains of food-borne pathogens since the late 1980s, PulseNet—the U.S. Centers for Disease Control and Prevention network for monitoring these pathogens—is instituting routine genome sequencing. With higher-resolution description of microbial diversity and of the dynamics of that diversity over time and across epidemiologic and demographic boundaries and evolutionary niches, we will gain even greater insights into the relationships of transmission routes and patterns of historical spread.

EPIDEMIC POTENTIAL

Defining pathogen transmissibility is a critical step in the development of public health surveillance and intervention strategies as this information can help to predict the epidemic potential of an outbreak. Transmissibility can be estimated by a variety of methods, including inference from the growth rate of an epidemic and the generation time of an infection (the mean interval between infection of an index case and infection of the people infected by that index case). Genome sequencing and analysis of a well-sampled population provide another method by which to derive similar fundamental epidemiologic parameters. One key measure of transmissibility is the basic reproduction number, defined as the number of secondary infections generated from a single primary infectious case. When the basic reproduction number is >1, an outbreak has epidemic potential; when it is <1, the outbreak will become extinct. On the basis of sequences from influenza virus samples obtained from infected patients very early in the 2009 H1N1 influenza pandemic, the basic reproduction number was estimated through a population genomic analysis at 1.2; this result provided greater confidence to estimates derived by traditional epidemiologic

FIGURE 474-4 ***A.*** Transmission events inferred from phylogenetic reconstruction of 154 *Vibrio cholerae* isolates from the seventh cholera pandemic. Date ranges represent estimated time to the most recent common ancestor for strains transmitted from source to destination locations, based on a Bayesian model of the phylogeny. *(Reprinted with permission from A Mutreja et al: Evidence for several waves of global transmission in the seventh cholera pandemic. Nature 477:462, 2011.)* ***B.*** Inferred Ebola virus spread in West Africa (Liberia, *red*; Guinea, *green*; and Sierra Leone, *blue*) by phylogeographic methods using virus genome sequences, dates, and an evolutionary model. The lines reflect spread between population centroids of each administrative region, going from the thin end to the thick end and colored by a time scale. *(Reprinted with permission from G Dudas et al: Virus genomes reveal factors that spread and sustained the Ebola epidemic. Nature 544:309, 2017.)*

data, which ranged from 1.4 to 1.6. In addition, with the assumption of a molecular clock model, sequences of H1N1 samples together with information about when and where the samples were obtained have been used to estimate the date and location of the pandemic's origin, providing insight into disease origins and dynamics. Because the magnitude and intensity of the public health response are guided by the predicted size of an outbreak, the ability of genomic methods to cast light on a pathogen's origin and epidemic potential adds an important dimension to the contributions of these methods to infectious disease epidemiology.

PATHOGEN EVOLUTION

Beyond describing transmission and dynamics, pathogen genomics can provide insight into the evolution of pathogens and the interactions of selective pressures, the host, and pathogen populations, which can have implications for clinical decision-making and the development of vaccines and therapeutics. From a clinical perspective, this process is central to the acquisition of antibiotic resistance, the generation of increasing pathogenicity or new virulence traits, the evasion of host immunity and clearance (leading to chronic infection), and vaccine efficacy.

Microbial genomes evolve through a variety of mechanisms, including mutation, duplication, insertion, deletion, recombination, and horizontal gene transfer. Segmented viruses (e.g., influenza virus) can reassort gene segments within multiply infected cells. The pandemic 2009 H1N1 influenza A virus, for example, appears to have been generated through reassortment of several avian, swine, and human influenza strains. Such potential for the evolution of novel pandemic strains has precipitated concern about the possible evolution to transmissibility of virulent strains that have been associated with high mortality rates but have not yet exhibited efficient human infectivity.

Experiments with H5N1 avian influenza, for example, have defined five mutations that render it transmissible, at least in ferrets—the animal model system for human influenza. Studies that examine the genomes of pathogens collected longitudinally from individual infections have similarly demonstrated the evolution of bacteria as they adapt from colonization to invasion and to new host environments and new immune and therapeutic pressures.

The continuous antigenic evolution of seasonal influenza offers an example of how studies of pathogen evolution can impact surveillance and vaccine development. Frequent updates to the annual influenza vaccine are needed to ensure protection against the dominant strains. These updates are based on anticipating which viral populations from a pool of substantial locally and globally diverse circulating viruses will predominate in the upcoming season. Toward that end, sequencing-based studies of influenza virus dynamics have shed light on the global spread of influenza, providing concrete data on patterns of spread and helping to elucidate the origins, emergence, and circulation of novel strains. Through analysis of more than 1000 influenza A H3N2 virus isolates over the 2002–2007 influenza seasons, Southeast Asia was identified as the usual site from which diversity originates and spreads worldwide. Further studies of global isolate collections have shed further light on the diversity of circulating virus, showing that some strains persist and circulate outside of Asia for multiple seasons.

Not only do genomic epidemiology studies have the potential to help guide vaccine selection and development; they are also helping to track what happens to pathogens circulating in the population in response to vaccination. By describing pathogen evolution under the selective pressure of a vaccinated population, such studies can play a key role in surveillance and identification of virulence determinants and perhaps may even help to predict the future evolution of escape from vaccine protection. The seven-valent pneumococcal conjugate vaccine (PCV-7) targeted the seven serotypes of *S. pneumoniae* responsible for the majority of invasive disease at the time of its introduction in 2000; since then, PCV-7 has dramatically reduced the incidence of pneumococcal disease and mortality. However, sequencing of >600 Massachusetts pneumococcal isolates from 2001 to 2007 has shown that, in the pneumococcal population, previously rare nonvaccine serotypes are replacing vaccine serotypes and that some vaccine strains have persisted despite vaccination by recombining the vaccine-targeted capsule locus with a cassette of capsule genes from non-vaccine-targeted serotypes.

The large collections of pathogen genome sequences are driving development of tools to decipher the genetic basis for antibiotic resistance, virulence, and infection risk. Some pathogens have distinct types of clinical manifestations, the basis for which we are just beginning to unravel with the aid of genomics. For example, *Listeria* is a food-borne pathogen that can cause both central nervous system infections and maternal/neonatal infections. Although all *Listeria* isolates are treated the same from a public health perspective, variation in outcomes exists and appears to be linked to the strains' genomic background. Molecular analysis of a national reference laboratory's collections of well-characterized specimens, based on the fraction of immunocompetent people in which they caused disease, revealed that some clonal complexes of *Listeria* appear to be more virulent than others. Linking epidemiology and comparative genomics then enabled enumeration of putative virulence factors that contribute to the clinical phenotypes as well as identification and confirmation of a novel gene cluster that mediates central nervous system tropism. This approach illustrates progress toward a future in which we can link pathogen identification with risk, thereby informing resource use and allocation.

GLOBAL CONSIDERATIONS

While cutting-edge genomic technologies are largely implemented in the developed world, their application to infectious diseases perhaps offers the biggest potential impact in less developed regions where the burden of these infections is greatest. This globalization of genomic technology and its extensions has already begun in each of the areas of focus highlighted in this chapter; it has occurred both through the application of advanced technologies to samples collected in the developing world and through the adaptation and importation of technologies directly to the developing world for on-site implementation as they become more globally accessible.

Genomic characterization of the pathogens responsible for such important global illnesses such as tuberculosis, malaria, trypanosomiasis, and cholera has led to insights in diagnosis, treatment, and infection control. For instance, with the increasing burden of drug-resistant tuberculosis in the developing world, a molecular diagnostic test has been developed to detect rifampin-resistant tuberculosis. The genetic basis for rifampin resistance has been well defined by targeted sequencing: characteristic mutations in the molecular target of rifampin, RNA polymerase, account for the vast majority of instances of rifampin resistance. At least in areas that can afford to implement it, a rapid, automated PCR assay that can detect both *M. tuberculosis* and a rifampin-resistant allele of RNA polymerase directly in clinical samples has been implemented in parts of Africa and Asia, transforming the recognition and management of incident tuberculosis and multidrug resistance where they are most prevalent. Since rifampin resistance frequently accompanies resistance to other antibiotics, this test can suggest the presence of multidrug-resistant *M. tuberculosis* within hours instead of weeks, without the infrastructure required for culture.

High-resolution genomic tracking of the spread of epidemics—from cholera to Ebola to Zika—has yielded insights into which public health measures may prove most effective in controlling local epidemics. Many genomic tracking efforts have involved close collaborations with local scientists and public health officials, and considerable investment in sequencing infrastructure in sub-Saharan Africa has made on-location epidemic tracking in the event of another such outbreak feasible. Such investment can not only enable real-time outbreak recognition and tracking but also provide the infrastructure needed to capitalize on the many other benefits of high-throughput sequencing as they are developed. Overall, sequencing efforts have become cheaper and have moved closer to point-of-care with each passing year. As these technologies synergize with efforts to globalize information-technology resources, global implementation of genomic methods promises to spread state-of-the-art methods for diagnosis, treatment, and epidemic tracking of infections to areas that need these capabilities the most.

SUMMARY

By illuminating the genetic information that encodes the most fundamental processes of life, genomic technologies are transforming many aspects of medicine. In infectious diseases, methods such as next-generation sequencing and genome-scale expression analysis offer information of unprecedented depth about individual microbes as well as microbial communities. This information is expanding our understanding of the interactions of microorganisms with each other, their human hosts, and the environment. Despite technological and financial barriers that continue to slow the widespread adoption of large-scale pathogen sequencing in clinical and public health settings, genomic methodologies have utterly transformed the research landscape in infectious disease and are beginning to make meaningful inroads into clinical settings. As even vaster amounts of data are generated, innovations in data storage, development of bioinformatics tools to manipulate the data, standardization of methods, and training of end-users in both the research and clinical realms will be required. The cost-effectiveness and applicability of whole-genome sequencing, particularly in the clinic, remain to be studied, and studies of the impact of genome sequencing on patient outcomes will be needed to clarify the contexts in which these new methodologies can make the greatest contributions to patient well-being. The ongoing efforts to overcome limitations through collaboration, teaching, and reduction of financial obstacles should be applauded and expanded. With advances in genomic technologies and computational analysis, our ability to detect, characterize, treat, monitor, prevent, and control infections has advanced rapidly in recent years and will continue to do so, with the hope of heralding a new era where the clinician is better armed to combat infection and promote human health.

475 The Role of Circadian Biology in Health and Disease

Jonathan Cedernaes, Kathryn Moynihan Ramsey, Joseph Bass

Circadian rhythms are autonomous, systemic cycles of behavior and physiology that synchronize organismal function at the cell and tissue level in anticipation of the 24-h rotation of the Earth. A common feature of modern "24/7" life is the routine disruption in these evolutionarily conserved endogenous circadian cycles, due to the rise in shift work, jet travel across time zones, exposure to blue light–emitting devices at night, and disrupted sleep. A transformation in understanding the molecular basis of circadian disorders has generated a new wave of research on metabolic disease, inflammation, aging, and cancer. This chapter provides an overview of (1) the basic biology of the circadian system; (2) primary circadian rhythm and interrelated sleep disorders; and (3) the role of the circadian system in both normal human physiology and disease states. Lastly, we review the rapidly emerging field of chronobiology as a pathway for novel diagnostic and therapeutic activity. A glossary of terms used in circadian biology is summarized in **Table 475-1**.

BASIC EVOLUTION AND STRUCTURE OF THE CIRCADIAN SYSTEM

A daily cycle between light and darkness existed long before the emergence of multicellular life. Eubacteria, the most ancient photosynthetic prokaryote, emerged in the geologic record more than 2.5 billion years ago at the same time as the first endogenous molecular clock. The co-occurrence in molecular evolution of clocks and photosynthesis hints at an interrelated and selective advantage to the clock and energetic processes—indeed clocks coordinate oxygenic reactions with periods of sunlight each day, and perturbation of clock cycles reduces fitness, reproduction, and survival. Additionally, clocks protect photosynthetic organisms from the DNA-damaging effects of sunlight by timing the production of DNA repair processes, such as photolyase-mediated repair, to the nighttime. Across billions of years of evolution, highly conserved circadian clocks (from "*circa diem*," "about a day") have been found in all photosensitive organisms, governing a wide range of behavioral, physiologic, and biochemical processes. A defining property of the circadian clock system is that it enables organisms to anticipate, rather than simply react to, daily changes in the external environment that are tied to the day-night cycle. In mammals, circadian systems are organized hierarchically with a light-responsive "master" circadian pacemaker located within the suprachiasmatic nucleus (SCN) of the anterior hypothalamus, which in turn presides over a network of both extra-SCN and peripheral clocks (see "Anatomic Organization of the Circadian Clock Network," below). Daily light exposure signals to the SCN and entrains the circadian system to the 24-h day (see "Entrainment and Measurement of the Circadian System," below), and the SCN in turn maintains synchrony of a diverse network of peripheral clocks via a variety of signals that have as yet to be fully identified, but which involve direct physiologic rhythms (core body temperature), the autonomic nervous system, and neuroendocrine signals, including cortisol as part of the hypothalamic-pituitary-adrenal (HPA) axis.

MOLECULAR ORGANIZATION OF THE MAMMALIAN CIRCADIAN CLOCK

At the molecular level, mammalian circadian rhythms are generated by a transcription-translation autoregulatory feedback loop. The forward limb of the clock is composed of the basic helix-loop-helix transcription factors (TFs) CLOCK (or its paralogue, NPAS2) and BMAL1, which drive expression of their own repressors (PER and CRY) in the negative limb, in a cycle that repeats itself every 24 h **(Fig. 475-1)**. A second short feedback loop involves CLOCK/BMAL1-mediated transcription of the retinoic acid–related orphan nuclear receptors ROR and REV-ERB, which activate and repress *Bmal1* transcription, respectively. Additional posttranslational regulation of the stability and degradation of core clock TFs includes phosphorylation by casein kinase 1 epsilon (CK1ε) and casein kinase 1 delta (CK1δ) and ubiquitination by FBXL3 and FBXL21. In addition to the ~24-h oscillation of core clock genes, a wide array of downstream clock-controlled genes (CCGs) exhibit broad amplitude in expression, ultimately giving rise to rhythmic physiologic processes. The core clock feedback loop and the induction of CCG rhythms also involves epigenetic mechanisms such as acetylation and methylation. The molecular circadian feedback loop is synchronized with sunrise each day by photosensitive melanopsin-expressing neurons within the retina. The retinohypothalamic tract (RHT) represents the input circuit to the SCN that maintains coherent organismal rhythms. Of note, mutations in several of these clock genes are associated with impaired circadian rhythms and physiology in humans (see "Primary Pathologies of the Circadian System," below). The importance of clock genes in the brain has been demonstrated by genetic studies, which have found that deletion of *Bmal1* in the whole brain or regions that span the SCN cause behavioral arrhythmicity, even when genetic ablation occurs late in life. Conversely, restoring *Bmal1* expression specifically in brain in adult clock mutant mice can rescue behavioral locomotor rhythms. Of note, whereas CLOCK normally heterodimerizes with BMAL1, NPAS2 is able to functionally substitute for CLOCK within pacemaker neurons; thus while mice lacking either *Clock* or *Npas2* genes maintain rhythmicity, the double mutants lacking both CLOCK and NPAS2 have impaired circadian rhythms of locomotor activity.

A major transformation in our understanding of circadian biology came with the discovery that the molecular clock network is present not only in the SCN, but also within most peripheral tissues, as well as in extra-SCN neurons in the brain. Interestingly, both the SCN and peripheral tissues exhibit a surprisingly large number of cycling transcripts at the genomic level, with approximately 3–16% of the mammalian transcriptome displaying a 24-h variation in mRNA expression levels across any given tissue, although the set of genes exhibiting circadian rhythmicity varies substantially between tissues depending upon tissue-specific functions. Posttranscriptional events such as RNA polyadenylation and mRNA translation also exhibit circadian variation, further increasing the repertoire of circadian processes at a cellular level. Thus, it is not surprising that among genes in the mammalian

TABLE 475-1 Glossary of Terms Used in Discussion of the Circadian System

TERM	DESCRIPTION
ASPD	Advanced sleep phase disorder (see text for description).
CBT	Core body temperature. Often used as an indicator of the circadian rhythm, but can be masked by sleep and exercise.
CCGs	Clock-controlled genes; output of the molecular clock.
Chronotype	Internal circadian rhythm of an individual determined by phase of entrainment, determining sleep propensity and timing of maximum alertness over a 24-h period.
Circadian period	Time required for one complete cycle or oscillation. Calculated by the time distance between two consecutive peaks or troughs of a circadian variable.
Circadian phase	Timing of the circadian rhythm. Defined by comparing, e.g., the peak (acrophase) or trough (bathyphase) to a fixed event, e.g., to a point in time. Synonymous with phase angle.
Circadian rhythm	A biological process that exhibits an endogenous, entrainable oscillation of approximately 24 h.
Circadian rhythm sleep disorders	Disorders of multiple etiology that have in common that they result in maladjustment of the biological clock with respect to the environment.
Constant routine	An experimental paradigm designed to study endogenous circadian rhythms in humans, by keeping behavioral and environmental factors constant. These paradigms thereby entail constant dim lighting, evenly distributed isocaloric energy intake, semi-recumbent posture, and forced wakefulness.
Desynchrony	Loss of synchrony occurring either between a rhythm and its Zeitgeber (external), or between two or more rhythms within an organism (internal).
Diurnal rhythm	An oscillation synchronized with the day/night cycle that repeats itself with a 24-h period. The rhythm does not have to persist when time cues (e.g., light) are absent.
DLMO	Dim-light melatonin onset; a marker of melatonin rhythm.
DSPD	Delayed sleep phase disorder (see text for description).
Entrainment	Synchronization of a circadian rhythm or other self-sustaining oscillation by a factor—Zeitgeber—that enforces the oscillator. Constant entrainment between the Zeitgeber and the oscillator results in a stable phase relationship between these entities.
Infradian rhythm	A recurrent cycle or period with a period length significantly greater than 24 h.
Melatonin	Hormone produced by the pineal gland (chemical name N-acetyl-5-methoxytryptamine); derived from L-tryptophan. Various forms of melatonin can be prescribed for CRSDs or sleep disorders.
Non-24-h rhythm disorder	A syndrome in which there typically are chronic 1- to 2-h daily delays in sleep onset and wake times in an individual living in society, e.g., due to complete blindness.
Peripheral clocks	Clocks presiding outside of the suprachiasmatic nucleus, the circadian system's master pacemaker.
PRC	Phase response curve; visual representation of how a particular manipulation (e.g., light) produces phase shifts as a function of the phase (i.e., circadian time) at which the manipulation occurs. Defining the PRC to light has enabled researchers to understand and predict how entrainment to light cycles is accomplished.
SCN	The suprachiasmatic nucleus or nuclei, also known as the master pacemaker in mammalian species. A bilateral set of nuclei positioned in the anterior ventral hypothalamus. Essential for entraining extra-SCN central and peripheral oscillators to the prevailing light-dark cycle via photic input from the retina.
Shift work	Work scheduled so that it occurs outside of the traditional work schedule of 9:00 A.M. to 5:00 P.M., or 6:00 A.M. to 6:00 P.M., depending on definition. Various forms of shift work exist, such as early morning, evening, or night shifts, as well as rotating shifts.
Ultradian rhythm	A recurrent cycle or period with a period significantly shorter than 24 h—e.g., a 2-h rhythm would exhibit 12 cycles within a circadian (24-h) rhythm.

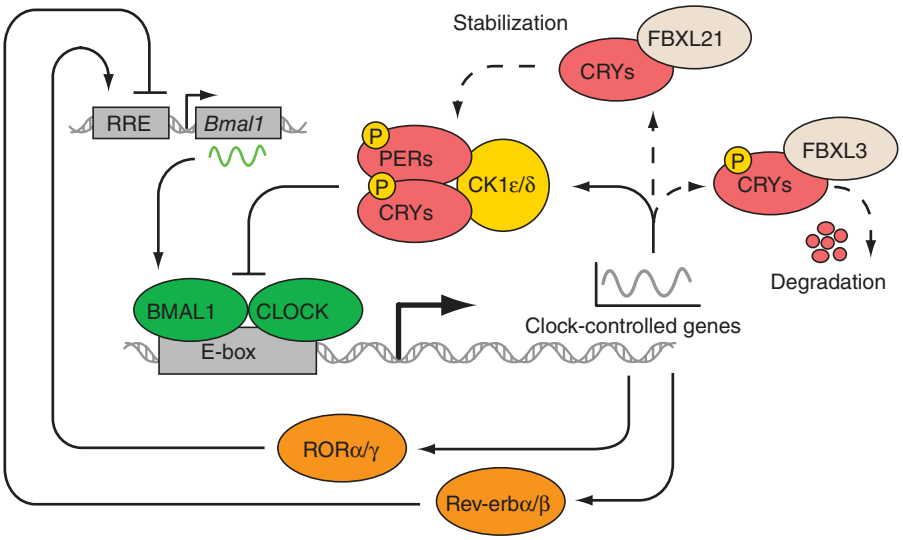

FIGURE 475-1 Central clock molecular mechanism. The core molecular clock machinery in mammals is encoded by interlocking transcription-translation feedback loops that oscillate with ~24-h periodicity. The transcription factors CLOCK and BMAL1 heterodimerize to drive transcription of downstream clock-controlled target genes containing E-box enhancer elements. Among these, the PER and CRY proteins multimerize and inhibit CLOCK/BMAL1 while RORs and REV-ERBs activate and inhibit, respectively, *Bmal1* transcription, resulting in rhythmic oscillations of clock-controlled and downstream target genes.

genome, almost half are considered to display circadian rhythms in at least one tissue.

ANATOMIC ORGANIZATION OF THE CIRCADIAN CLOCK NETWORK

Understanding the circuit organization of the circadian clock within the brain is increasingly relevant in understanding how the master circadian pacemaker center within the SCN regulates feeding, sleep-wake activity, energy expenditure, endocrine processes, and metabolism (Fig. 475-2). Identification of the SCN as the master pacemaker was first established by the observation that SCN lesioning induced complete loss of rhythms of locomotor activity and endocrine hormone secretion. The ventral "core" region of the SCN, which is composed of neurons producing vasoactive intestinal polypeptide (VIP), receives photic information directly from the retina through the RHT. At the molecular level, circadian gene transcription is induced within the SCN through the initial activation of immediate early genes, such as *Per1*, *Per2*, *c-fos*, and *jun*. Cells within the "core" region of the SCN then signal primarily via GABA-ergic neurotransmitter release to synchronize the cells within the "shell" region of the SCN, which produce the neuropeptide arginine vasopressin (AVP).

The SCN communicates to extra-SCN and peripheral clocks through both secreted factors and direct neuronal projections. The former was elegantly proven by the ability of SCN grafts to partially restore locomotor rhythms in an SCN-lesioned host. Efferent nerve outputs predominantly arise from the AVP-producing shell region of the SCN, although some output is also derived from the VIP-predominated core. The SCN projects to several hypothalamic relay regions, including the median preoptic nucleus, the subparaventricular zone (SPZ), the dorsomedial hypothalamus (DMH), and the paraventricular nucleus of the hypothalamus (PVH). These, in turn, regulate output to both sleep- and wake-promoting regions, as well as to regions involved in autonomic regulation and feeding. The SCN is thereby thought to promote sleep through the transmission of neural signals that terminate in the sleep-promoting ventrolateral preoptic nucleus (VLPO), i.e., one of the brain regions that is active during sleep. In contrast, the SCN promotes wakefulness during the active phase by transmission of neural signals that—by passing through regions such as the DMH—terminate in wake-promoting regions, including the locus coeruleus, lateral hypothalamic nucleus, ventral tegmental area, and dorsal raphe nucleus.

The SCN also signals via noradrenergic fibers to the pineal gland, thereby regulating the circadian production of the hormone melatonin. SCN control of the nighttime rise in pineal melatonin release (in both diurnal and nocturnal animals) is mediated through a pathway involving the PVH. Of note, artificial light at night is able to delay the secretion of melatonin, ultimately affecting sleep (see "Endocrine Systems Regulated by the Circadian Clock," below). Melatonin plays a complex role in the circadian system since the MT1 and MT2 melatonin receptors are expressed on the SCN itself; thus melatonin feeds back to modulate circadian outputs to other cells in the brain and body.

Neuronal output from the SCN also reaches the periphery, i.e., to the adrenal glands, the liver, and the pancreas. The SCN produces rhythmic variation in multiple neuroendocrine axes, producing daily rhythms of gonadotropin, thyrotropin, and somatotropin. Prominent hypothalamic-pituitary-adrenal (HPA) axis rhythms ultimately give rise to daily variation in diverse pathways essential for hemodynamic

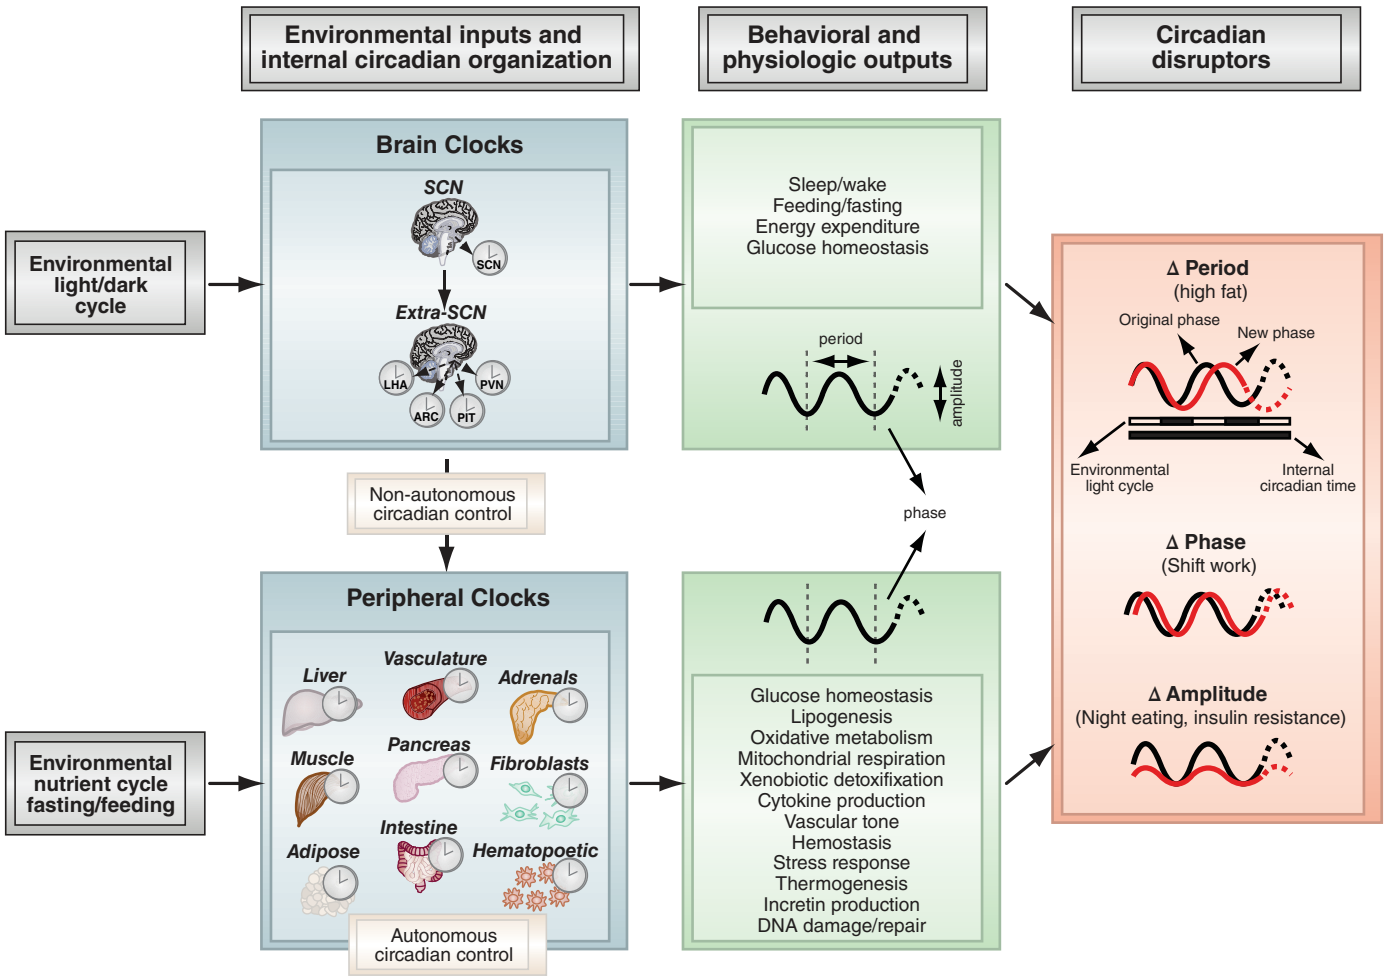

FIGURE 475-2 Central and peripheral clocks coordinate environmental cues with behavior and physiologic outputs. Light entrains the master pacemaker neurons in the SCN, which subsequently synchronizes extra-SCN and peripheral clocks. Brain clock output includes sleep-wake, fasting-feeding, and energy expenditure cycles, while peripheral clock output includes a wide range of physiologic processes, including glucose homeostasis, oxidative metabolism, cytokine production, and stress response. The right column indicates different ways that circadian disruptors, such as diet, shift work, or other circadian rhythm sleep disorders, may impact the clock—i.e., by changing circadian period, phase, or amplitude.

stability, metabolism, and inflammation. These rhythms originate with SCN control of corticotropin-releasing hormone (CRH)-producing cells in the PVH, which induce daily oscillations of both pituitary adrenocorticotropic hormone (ACTH) and adrenal cortisol. Highlighting the importance of SCN output for peripheral rhythms, there is a dramatic reduction in the number of transcripts that exhibit circadian rhythms in the liver following SCN ablation in mice. Nonetheless, when the autonomous clock in the liver is ablated in mice, some key clock transcripts such as *Per2* are still able to cycle as long as the core body temperature rhythm persists. Whereas the SCN is exclusively entrained by light, meal timing is able to signal circadian time directly to the liver. Thus, shifted meal timing as occurs during shift work or jetlag can uncouple peripheral clocks from the central pacemaker. In comparison to peripheral tissue clocks, the SCN is also resistant to phase shifts induced by temperature. This is consistent with the concept that the SCN generates the core body temperature rhythm as one of the major mechanisms to signal circadian time to peripheral clocks.

ENTRAINMENT AND MEASUREMENT OF THE CIRCADIAN SYSTEM

Under normal light-dark cycles, the circadian system is corrected or "entrained" on a daily basis, producing diurnal rhythms of 24 h. Such signals of entrainment are called Zeitgebers ("time-giver" signals) and include light exposure, meal timing, and activity patterns. Light serves as the dominant Zeitgeber for the circadian system, and a breakthrough in understanding photoentrainment in mammals came with the discovery of the melanopsin system, which is composed of a specialized class of photosensitive retinal ganglion cells that expresses the blue-light sensitive photopigment melanopsin in the inner retina, separate from the photoreceptive rods and cones. Blue light around this wavelength (~480 nm) suppresses melatonin and promotes subjective and objective (electroencephalography-assessed) wakefulness.

The ability of light to entrain the circadian system functions according to a so-called phase response curve (PRC). When light exposure occurs prior to the critical phase of the core body temperature (CBT), defined by the CBT's minimum, light produces a phase delay in the circadian rhythm. Conversely, light exposure after this critical period causes phase advances. The circadian system can respond even to small changes in light intensity (e.g., dim light at ~100 lux can produce half of the phase delay compared with an almost 100-fold greater light exposure). This responsiveness is furthermore affected by our genetic makeup, as variants in clock genes can modulate the response of the human circadian system to light.

When an organism is placed in an environment without Zeitgebers, the circadian rhythm is said to free-run, as it will rely on the endogenous rhythm of the circadian system. In humans, the study of endogenous circadian rhythms can be achieved by using a so-called constant routine. In these paradigms, subjects are maintained in a constant semi-recumbent posture, meals are provided on an hourly basis, light is constantly kept below the level which phase shifts the SCN, and circadian rhythms are assessed by measuring CBT, melatonin, or peptidergic hormone rhythms. In animals, circadian rhythms are instead studied by examining behavior and physiologic responses after 30–36 h of complete darkness, and endogenous rhythms are assessed by measuring voluntary locomotor activity. From these measurements, key properties of the circadian system can be ascertained, such as period length (peak-to-peak or trough-to-trough time), amplitude (peak-to-trough difference) and phase (timing of peak or trough in relation to a reference point) (Fig. 475-2).

These studies have revealed that the endogenous human circadian clock runs with a period length of approximately 24.2 h (compared with mice that run at ~23.5 h, depending on the strain). Evidence indicates that human females may have a slightly shorter circadian clock (24.1 vs 24.2 h). Notably, interindividual variability in the endogenous circadian period length is further diversified by the existence of genetic polymorphisms in clock genes (see below). These gene variants can confer extremes in endogenous circadian period as well as phase; the latter can be advanced or delayed by about 3–4 h in each direction. This is due both to altered circadian rhythms at the cell level and to altered SCN responsiveness to entrainment by light. For instance, *PER3* exists in a variable-number, tandem-repeat polymorphism. Individuals homozygous for a *PER3 5/5* genotype have been reported to be more responsive than *PER3 4/4* homozygous individuals to the melatonin-suppressing effect of evening blue light exposure.

Using specifically developed questionnaires to establish preferred sleep-wake timing, individuals can be categorized into so-called morningness-eveningness types or chronotypes. The most commonly used questionnaires are the Horne-Östberg morningness-eveningness questionnaire (MEQ) and the Munich ChronoType Questionnaire (MCTQ). The MEQ is composed of 19 questions regarding traits distinguishing morning-type compared with evening-type individuals, such as preferred waking time. In contrast, the MCTQ centers on the midpoint of sleep as a circadian marker, queries age and sex across a range of geographical locations, and can be used to ascertain differences between socially imposed sleep patterns (e.g., on working days) and sleep patterns on free days (the difference constituting so-called social jetlag). According to MCTQs obtained from primarily European populations, ~1% of the general population goes to bed before 10:00 PM and about 8% after 03:00 AM. Differences in chronotype are linked to altered circadian timing—including peak levels of melatonin, which can vary by up to 4 h between extreme morning and evening types. Extreme chronotypes have also been shown to be linked to various traits; i.e., low morningness scores have been associated with greater tolerance to shift work.

Melatonin is one of the most commonly used peripheral markers of an individual's circadian rhythm, reflecting the rhythmic function of the SCN. Circadian rhythms of melatonin can be measured in saliva or plasma, while 6-sulphatoxymelatonin (aMT6S), a metabolite generated from the breakdown of melatonin, can also be measured in urine. Accurate estimations of melatonin rhythms are often obtained by analyzing the dim light melatonin onset (DLMO), which as the name implies does not require an entire 24-h sampling, making this marker useful in both the clinical and research setting. In normally entrained individuals, the DLMO can be used to ascertain whether an individual's circadian rhythm is phase advanced or delayed, and this onset typically occurs ~2 h before the onset of sleep. The midpoint of sleep—the main marker used by the MCTQ—also strongly correlates with melatonin onset.

The CBT is also often utilized as an indicator of the circadian rhythm, and even though the outcome is more variable when using the CBT, it usually correlates well with the phase obtained using the melatonin rhythm. The CBT, however, can be masked by factors such as sleep, food intake, and activity. CBT can be recorded and registered wirelessly with relative ease. In humans, CBT can for example be recorded via rectal thermometers or probes that are swallowed to pass through the gastrointestinal tract. When humans are studied under normal conditions with normal lighting and sleep duration from 2300 to 0700 h, the CBT reaches around 37.2°C by 0900 h, and from there continues to rise slowly until it reaches 37.4°C around 11 h later. The CBT then drops to the daily low of 36.5°C in the early morning (0400 h).

Given the interrelationship between the circadian system and sleep-wake systems, researchers have developed paradigms that uncouple the circadian system from sleep-wake states, enabling the study of the contribution of the circadian system to investigated parameters across the entire sleep-wake cycle. These paradigms are known as "forced desynchrony" protocols and involve enforcing a significantly shortened (e.g., 20 h) or prolonged (e.g., 28 h) day length upon individuals. These protocols thus attempt to approximate what occurs during rotating shift work or "jetlag," e.g., when travel across several time zones suddenly shifts the light-dark and behavioral cycle drastically away from the entrained 24-h rhythm. As described below, forced desynchrony protocols have contributed to uncovering how the circadian system regulates parameters such as cognitive performance, subjective alertness, and metabolic and cardiovascular health.

PRIMARY PATHOLOGIES OF THE CIRCADIAN SYSTEM (SEE ALSO CHAP. 27)

An overarching term for disorders of the circadian system is *circadian rhythm sleep disorders* (CRSD). These disorders have become

increasingly recognized as important factors in a number of conditions; a unifying feature of CRSD involves a mismatch between subjective behavioral and physiologic rhythm with the environmental light-dark or social activity-rest cycle (i.e., the body clock is out of sync with the external light-dark cycle). CRSDs can arise either due to misalignment of an exogenous environmental factor, such as light, with the intrinsic circadian cycle, or due to misalignment of activity/rest cycle in relation to endogenous circadian timing (e.g., shift work or jetlag). In addition to such environmental or exogenous conditions causing circadian disruption, in some cases intrinsic circadian timing is altered in relation to the external environment, as in the case of endogenous circadian disorders that include those caused by mutations in core clock genes. Under conditions of intrinsic circadian abnormalities, it is often exceedingly difficult for individuals suffering from CRSDs to try to properly realign themselves, and these disorders often result in adverse effects such as sleepiness or depressed mood. Societal and economic consequences also are common; these can result in the individual being unable to maintain a job or be unable to attend at regular school hours. The criteria for CRSDs based on the International Classification of Sleep Disorders (ICSD) is shown in **Table 475-2**.

Animal models have greatly advanced our understanding of how core molecular clock components contribute to maintaining normal sleep-wake/rest-activity cycles **(Table 475-3)**. For example, *Clock*$^{\Delta 19/\Delta 19}$ mice have reduced total sleep duration and less induction of REM sleep in response to sleep deprivation. Further, mice that lack *Bmal1* have increased total sleep time, but it is more fragmented and lacks clear 24-h sleep-wake rhythms, and mice lacking the repressors *Cry1* and *Cry2* are not only arrhythmic but spend more time in non-REM sleep. Finally, while ablation of the circadian gene *Dbp* does not alter the specific duration of sleep stages, it does lead to an altered circadian sleep-wake distribution, with more sleep during their normal wake period and vice versa. Consistent with a key role of clock genes in regulating sleep-wake behavior, human genetic studies of twins have found that up to half of the variation in diurnal preference is heritable. Established genetic variants associated with diurnal preference and circadian sleep disorders are listed in **Table 475-4**.

Delayed Sleep Phase Disorder Delayed sleep phase disorder (DSPD) is one of the more common circadian rhythm sleep disorders and is characterized by chronic and significant delays in both sleep onset and wake times compared to normal "socially acceptable" sleep-wake hours (i.e., scoring as "extreme night owls" on morningness-eveningness preference tests). Rhythms of CBT and melatonin levels in plasma and urine are likewise delayed and the circadian period (tau) is longer in DSPD. Onset of DSPD most commonly occurs during adolescence or early adulthood. While the precise etiology of DSPD is not well established, it has been associated with polymorphisms within the circadian clock genes *CLOCK* and *PER3*. An integrated behavioral and pharmaceutical therapeutic approach has been found to be most effective at treating individuals with DSPD. Such treatments include a combination of bright-light therapy soon after waking in the morning (and/or dark-room therapy in the evening) and melatonin administration in the evening several hours prior to the onset of sleep. These approaches aim to realign endogenous circadian rhythms with the desired sleep-wake schedule. As individuals suffering from DSPD also phase delay more rapidly, this explains why attempts to phase advance their sleep schedule can be difficult, as well as why relapse can easily occur after initial treatment.

TABLE 475-2 Criteria for Circadian Rhythm Sleep Disorders

CRITERIA	DESCRIPTION
A	A persistent or recurrent pattern of sleep disturbance due primarily to one of the following: • Alterations of the internal circadian timekeeping system. • Misalignment between endogenous circadian rhythms and exogenous factors that affect the timing or duration of sleep.
B	A circadian-related sleep disruption that leads to insomnia, excessive daytime sleepiness, or both.
C	A sleep disturbance that is associated with impairment of social, occupational, or other areas of functioning.

Advanced Sleep Phase Disorder Another circadian rhythm sleep disorder whereby one gets the correct amount and quality of sleep but at a shifted time is advanced sleep phase disorder (ASPD). Individuals with ASPD experience an advance in their major sleep episode in relation to the desired clock time. Thus, this disorder typically results both in very early evening bedtimes and morning awakenings (e.g., "extreme early birds"), resulting in reduced quality of life due to excessive sleepiness during early evening, even in social situations. Individuals with ASPD also have phase-advanced temperature and melatonin rhythms in parallel with their earlier sleep onsets. ASPD occurs more often in older individuals, although early-onset autosomal dominant familial variants (familial advanced sleep phase syndrome [FASPS]) have also been associated with mutations in either the *PER2* or the casein kinase 1δ (CK1δ) genes. PER2 is critical for SCN resetting by light, and the identification of PER2 mutations in familial ASPD was the first in which clock genes were tied to a CRSD. Such mutations have been found to be able to shorten the endogenous circadian period to about 23.3 h compared with the normal 24.2-h period length. Accordingly, ASPD can be distinguished from other non-circadian sleep disorders by an early onset of dim-light melatonin secretion, a reliable marker for the timing of endogenous circadian rhythms both in the research laboratory as well as in the clinical setting. Polysomnography (PSG) or actigraphy are not required for diagnosing ASPD, although actigraphy may be significantly more feasible for long-term analysis of circadian timing of sleep. Treatments for ASPD include bright light or blue-enriched phototherapy in the evening hours to delay the phase of the circadian clock to a later hour.

Non-24-h Sleep-Wake Rhythm Disorder Individuals with non-24-h sleep-wake rhythm disorder ("non-24"), otherwise known as free-running disorder (FRD), have endogenous circadian rhythms that are not synchronized with the external 24-h day-night cycle due to an inability to readjust the circadian clock to the 24-h day on a daily basis. This most commonly occurs in individuals who are completely blind (i.e., lacking all photoreceptors) since they are unable to respond to daily light cues, which normally would reset the endogenous circadian clock on a daily basis (although the condition has also been reported in sighted individuals). Instead, the sleep-wake period length corresponds to the individual's endogenous circadian rhythms, which are typically slightly longer than 24 h, thereby shifting sleep and wake cycles over time in relation to the light-dark cycle. Instead of sleeping at the same time each day, their sleep time would gradually be delayed each day until their sleep period literally goes "around the clock." Depending on the individual's endogenous rhythm, the individual will take a given number of days to re-align his or her endogenous phase (in a 360° phase plot) with the zero time point in the exogenous 24-h light-dark cycle. For example, if an individual has an endogenous 24.5-h rhythm, it would take that individual 48 days to cycle from one cycle to the next. Because of this chronic cycling, prominent symptoms of non-24 include sleep-wake cycle disruption (insomnia and daytime sleepiness), impaired alertness and mood levels, and severe difficulties partaking in normally scheduled work, school, or social activities. Non-24 can be diagnosed following diurnal analysis of an individual's melatonin or cortisol rhythms, in combination with analyses of sleep diaries where the sleep onset and offset can be visualized over time to identify the free-running period. Treatments for sighted non-24-h patients include a combination of bright light therapy with appropriately timed melatonin administration, while melatonin and dual melatonin (MT1 and MT2) receptor agonist administration in completely blind non-24-h patients has been shown to entrain free-running rhythms and improve symptoms.

Shift Work Sleep Disorder Given the increased prevalence of shift work in today's 24/7 society and the accumulating evidence for increased incidence of sleep and metabolic disorders, including obesity, diabetes, cardiovascular disease, and cancer, in shift workers, the need to develop effective treatments for shift work sleep disorder (SWSD) are

TABLE 475-3 Animal Models of Genetic Circadian Disruption

GENE	AVERAGE CIRCADIAN TIME OF PEAK TRANSCRIPT LEVEL		ALLELE	MUTANT PHENOTYPE
	SCN	PERIPHERY		
Bmal1 (Arntl)	15–21	22–2	*Bmal1*$^{-/-}$	Arrhythmic
CK1δ (Csnk1δ)	No rhythm	No rhythm	*Csnk1δ*$^{+/-}$	0 to 0.5-h shorter period
CK1ε (Csnk1ε)	No rhythm	No rhythm	*CK1ε*^{tau}	4-h shorter period
CK1ε	—	—	*CK1ε*$^{-/-}$	0.2- to 0.4-h longer period
Clock	No rhythm	21–3	*Clock*$^{-/-}$	0.5-h shorter period
—	—	—	*Clock*$^{\Delta 19/\Delta 19}$	4-h longer period/arrhythmic
Clock/Npas2	—	—	*Clock*$^{-/-}$*/NPAS2*$^{-/-}$	Arrhythmic
Cry1	8–14	14–18	*Cry1*$^{-/-}$	1-h shorter period
Cry2	8–14	8–12	*Cry2*$^{-/-}$	1-h longer period
—	—	—	*Cry2*^{A260T}	0.2-h shorter period
Dbp	—	—	*Dbp*$^{-/-}$	0.5-h shorter period
Npas2	N/A	0–4	*Npas2*$^{-/-}$	0.2-h shorter period
Per1	4–8	10–16	*Per1*$^{-/-}$	0.7-h shorter period
—	—	—	*Per1*^{brdm1}	1-h shorter period
—	—	—	*Per1*^{ldc}	0.5-h shorter period/arrhythmic
Per2	6–12	14–18	*Per2*^{brdm1}	1.5-h shorter period/arrhythmic
—	—	—	*Per2*^{ldc}	Arrhythmic
Per3	4–9	10–14	*Per3*$^{-/-}$	0 to 0.5-h shorter period
Rev-erbα (Nr1d1)	2–6	4–10	*Rev-erbα*$^{-/-}$	0.5-h shorter period/disrupted photic entrainment
Rorα	6–10	Arrhythmic/various	*staggerer*	0.5-h shorter period/disrupted photic entrainment
Rorβ	4–8	18–22	*Rorβ*$^{-/-}$	0.5-h longer period
Rorγ	N/A	16–20/various	*Rorγ*$^{-/-}$	Normal behavior

increasingly important. Shift work sleep disorder is at its core defined by the primary symptom of either insomnia or excessive sleepiness, occurring as a transient phenomenon in relation to work that usually is scheduled during the habitual hours of sleep or comprises irregular work hours. The symptoms may result from recovery of sleep having to consume a large proportion of the individual's free time, which may produce negative social consequences such as difficulties maintaining social relationships. Older individuals are typically at an increased risk of SWSD due to age-associated decline in the ability to maintain sleep during normal waking hours. Since the symptoms likely arise from a misalignment of sleep-wake rhythms with the external light-dark cycle, therapeutic approaches aim to realign endogenous circadian rhythms with the sleep cycles dictated by work. In addition to optimizing the sleep environment at home to minimize disruptions, timed bright light therapy can help individuals with SWSD—i.e., for night workers, intermittent bright light exposure during the night and avoidance of bright light during the morning, even on days off, has been shown to improve sleep and feelings of alertness. Melatonin prior to bedtime may also help improve symptoms of SWSD. Genetic screening combined with chronotype questionnaires may become useful tools for determining whether a given individual is suited for shiftwork. For instance, a twin study indicated that a genetic variant of the circadian gene *DEC2* was associated with reduced sleep duration, and with shorter recovery sleep following extended sleep deprivation. More studies may reveal additional genetic variants that confer an advantage to repeated phase advances and phase delays as typically occurs in shift work.

Irregular Sleep-Wake Rhythm Damage to the SCN can produce arrhythmicity in animals and is thought to be one of the possible underlying reasons for the temporally disorganized sleep-wake pattern that characterizes the disorder known as irregular sleep-wake rhythm (ISWR). Other contributing factors may be a reduced responsiveness to entraining signals such as light and physical activity, as well as a decreased exposure to such signals as often occurs with increasing age due to, for example, increased risk of poor health and impaired mobility. Whereas the total sleep time per 24 h may be comparable, there is

TABLE 475-4 Mutations and Gene Variants Linked to Sleep-wake Disorders and Diurnal Preference

GENE	POSITION	POPULATION	SYNDROME/SLEEP PREFERENCE

a relative absence of a circadian pattern to the sleep-wake cycle. Sleep timing throughout the sleep-wake cycle can be shortened—sometimes close to randomly distributed—instead of occurring in several distinct bouts. ISWR is often associated with neurologic impairment, foremost Alzheimer's disease in older age; however, ISWR can also occur in individuals with poor sleep hygiene. The most effective treatments for ISWR involve not pharmacotherapy but rather multimodal interventions such as increased light exposure, improved sleep hygiene, and promotion of social and physical activities.

Jetlag Most have experienced symptoms associated with jetlag, including insomnia, day-time sleepiness, and fatigue, when traveling from one time zone to another, as one's endogenous circadian rhythms are not yet aligned, or entrained, to the new external light-dark cycle. This is due to the slowness of the circadian system to adapt to the new time zone: typically, the human circadian system is able to shift ~1.5 h a day in the westward direction (i.e., a phase delay), whereas it shifts more slowly (about 1 h daily) with eastward direction of travel (i.e., achieving a phase advance). Importantly, the symptoms are distinguished from the more short-lived symptoms that can partially result from exposure to traditional airplane cabin conditions, including abdominal distention, dependent edema, muscle cramps, headaches, nausea, and, intermittent dizziness. Usually symptoms of jetlag abate within the first couple of days after traveling, and may present themselves after a first night of good sleep (which is more dependent on a high build-up of homeostatic sleep pressure). Older individuals (age >50) appear to be more at risk. While symptoms are transient, therapeutic approaches can alleviate or temper some of the side effects of travel by hastening synchronization of the internal and external circadian cycles. Behavioral treatments include appropriately timed bright-light exposure and avoidance of bright light during the night time in the new destination, while pharmacologic approaches include timed melatonin administration before bedtime both prior to and following travel, resulting in improved sleep quality and decreased night waking.

Social Jetlag Individuals with a late chronotype are prone to suffer from "social jetlag," a phenomenon in which individuals are forced to awaken at a point at which their bodies are entrained to be asleep due to discrepancy between alignment of social and biological time. Social jetlag can be estimated using questionnaires, such as the MCTQ, to compare sleep timing on non-free compared with free days. This has established that a large proportion of the European population suffers from 2 or more hours of social jetlag. Chronic social jetlag has been associated with an increased risk of developing obesity and the metabolic syndrome, as well as with greater alcohol consumption and smoking.

The aforementioned categories of defined clinical circadian disorders have been traditionally established based upon consideration of the endogenous behavioral and physiologic cycles (primarily of melatonin and temperature) with the external 24-h light-dark cycle. In the following sections, we build on the concepts of circadian behavioral disorders to consider new and emerging insight into the role of circadian disruption in organismal homeostasis **(Figs. 475-3 and 475-4)**, and the availability of genetic strategies to dissect the interrelationship between clock function, health, and disease.

ROLE OF THE CLOCK SYSTEM IN PHYSIOLOGY

Endocrine Systems Regulated by the Circadian Clock In addition to regulation of behavioral rhythms such as sleep/wake and fasting/feeding cycles, the circadian clock also regulates rhythms of the endocrine system. Cortisol rhythms are regulated through a feedback

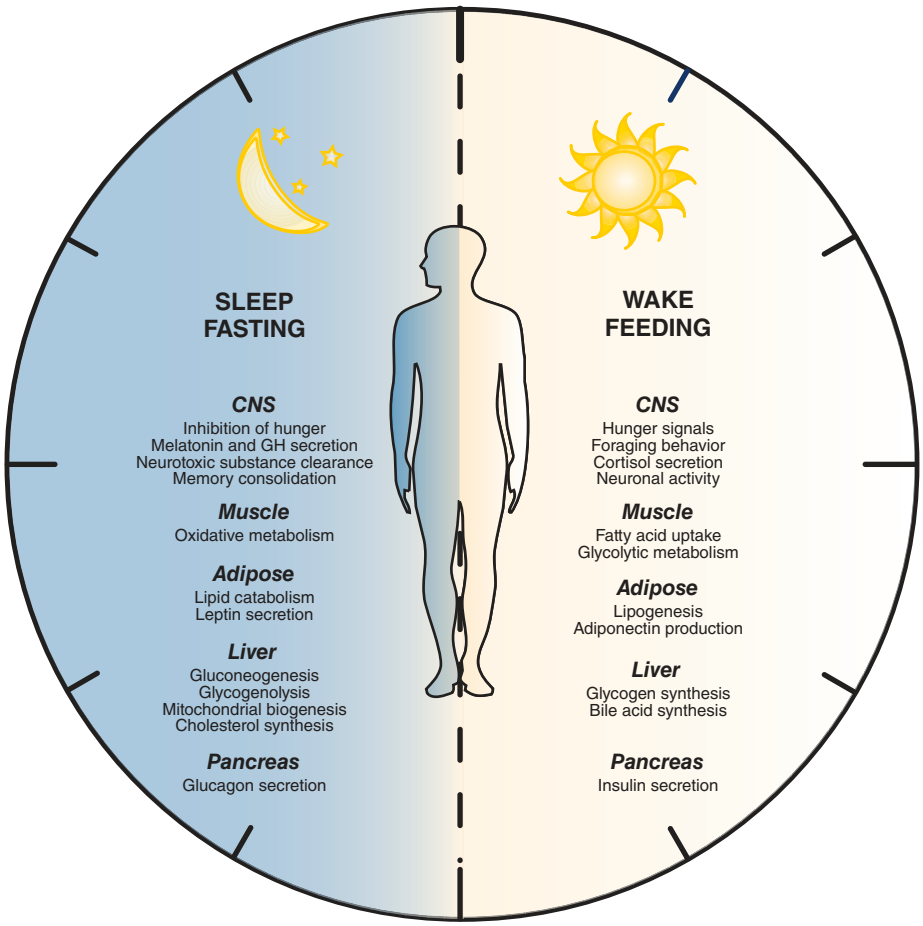

FIGURE 475-3 The circadian clock partitions behavioral, physiologic, and metabolic processes according to time of day. The partitioning of metabolic processes to appropriate times of day is critical for the maintenance of health from cellular to mammalian organisms. This figure highlights which processes peak within CNS, muscle, adipose, liver, and pancreas during either the sleep-fasting or wake-feeding cycle in humans.

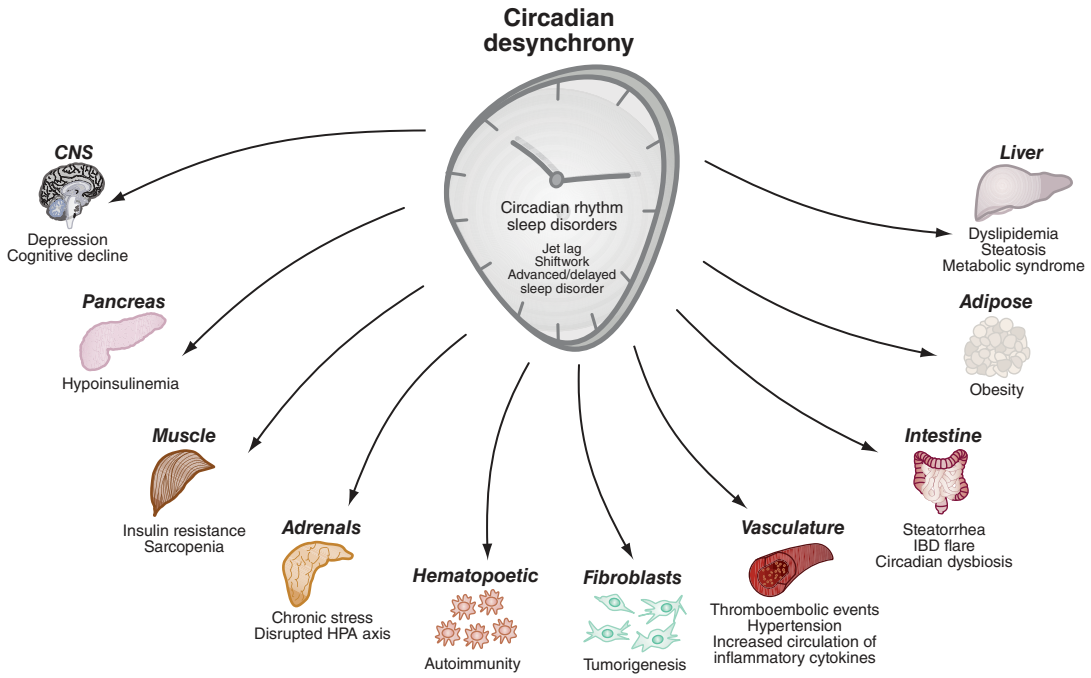

FIGURE 475-4 Pathologies resulting from circadian desynchrony. Circadian rhythm sleep disorders, including advanced/delayed phase sleep disorder, jetlag, social jetlag, and shift work, result in a desynchrony between the environmental light-dark cycle "time" and the endogenous clock "time." Pathologies can thus arise through misalignment imposed by exogenous factors (e.g., altered light cycle, feeding rhythm) as well as endogenous factors, such as mutations in core clock genes. Such desynchrony results in a host of wide-ranging pathologies across multiple tissues, including hypoinsulinemia (pancreas), disrupted HPA axis, autoimmunity, hypertension, obesity, and metabolic syndrome.

loop known as the hypothalamic-pituitary (HPA) axis **(Chap. 379)**. Hypothalamic secretion of CRH and AVP promotes secretion of pituitary adrenocorticotropic hormone (ACTH), which in turn regulates rhythmic cortisol secretion from the adrenal cortex. Cortisol release increases towards the morning, and this increase is believed to prepare the brain and peripheral tissues for daytime activity and food intake. Daytime sleep can blunt circulating cortisol levels, presumably through the occurrence of non-REM sleep. AVP secretion in mice occurs prior to sleep to promote water intake, thereby preventing dehydration during the sleep period. Several hormonal systems are in fact influenced more by sleep than by circadian rhythms. For instance, secretion of growth hormone (GH) is profoundly blunted during acute overnight wakefulness. The secretion of this hormone is primarily dependent on the occurrence of slow-wave sleep, which is a homeostatically driven sleep stage that occurs primarily in the first part of the sleep period. Cortisol also exhibits a peak close after wakefulness: the cortisol awakening response (CAR). This peak seems to be independent of a circadian rhythm, as the CAR is severely blunted by acute overnight wakefulness. Curtailed sleep and overnight wakefulness increase the activity of the HPA axis and may increase diurnal cortisol levels. Sleep also influences melatonin amplitude, such that sleep deprivation can increase melatonin levels. In working environments, the effects of curtailed sleep are often confounded by mistimed exposure to light. Even low levels of light are able to potently suppress melatonin secretion. Together with altered timing in light exposure, perturbed hormonal levels may represent a mechanism through which altered timing and duration of sleep may impact central and peripheral circadian oscillators.

Centrally controlled rhythms of melatonin and cortisol are considered key regulators of extra-SCN and peripheral oscillators. Glucocorticoid receptors exist in both the central nervous system and in peripheral tissues such as skeletal muscle, liver, and adipose tissue. Following acute shifts in light-dark or feeding cycles, 24-h rhythms of circulating cortisol appear to shift more slowly than other rhythms and may thus contribute to adverse effects of circadian misalignment by hampering proper realignment of peripheral clocks. Glucocorticoids shift clock gene expression in muscle, kidney, and lung, while the powerful synthetic glucocorticoid dexamethasone is able to synchronize (e.g., reset) circadian rhythms of cells in culture, including liver cells. Consistent with a role for glucocorticoid regulation of the clock, both adrenalectomy, which results in a lack of cortisol, and exogenous corticosteroid supplementation significantly disrupt the circadian clock system.

Several peripherally produced hormones and peptides are not only produced rhythmically but can also feedback to central clocks, including the SCN. For instance, both cortisol and thyroid hormones regulate their own rhythmic synthesis by feedback to central brain regions, i.e., the hypothalamus (for cortisol) and pituitary (for both hormones). Several other peripherally produced factors have been proposed to influence the central clock, including fatty acids produced by the adipose tissue and fibroblast growth factor 21, a hormone primarily produced by the liver. Peripheral hormones that signal energy state and hunger also exhibit circadian rhythms. The most extensively studied hormones are leptin, which is released from white adipose tissue cells, and ghrelin, which is released from the upper fundus region of the stomach. Ghrelin also exhibits significant peaks related to anticipated meal timing, which persist for several days of fasting in humans. Circulating rhythms of leptin and ghrelin are disrupted in circadian mutant mice and are also perturbed in humans subjected to circadian misalignment. For instance, *Per* and *Cry* mutant mice exhibit severely blunted leptin rhythms, and wild-type mice exposed to jetlag—through repeatedly altered light-dark cycles—show a reduced wake-associated decrease in leptin. Similarly, humans forced to live 28-h days exhibit increased 24-h profiles of ghrelin, and conversely decreased levels of leptin. Ghrelin and leptin signal to several regions of the brain, including integrative appetitive regions of the hypothalamus such as the arcuate and paraventricular region. Through actions in several such central sites, these hormones influence rhythms of food intake and energy homeostasis in a nutrient-dependent manner.

Role for the Clock in Metabolic Homeostasis Circadian control of glucose homeostasis has long been recognized, as early studies demonstrated variation in glucose tolerance and insulin action across the day. For example, oral glucose tolerance is impaired in the evening and afternoon compared with the morning due to a combination of circadian control of both peripheral insulin sensitivity and

pancreatic β-cell insulin secretion. Another example is the "dawn phenomenon," whereby glucose levels peak prior to the onset of activity. Further, destruction of the SCN has been shown to abolish circadian regulation of glucose metabolism in rats, and daily cycles of insulin secretion and glucose tolerance are often perturbed in patients with type 2 diabetes. Changes have also been observed in first-degree relatives of patients with type 2 diabetes, possibly highlighting a key hereditary component of the circadian clock in the pathogenesis of type 2 diabetes.

Ablating clock genes in mice has revealed a key function for both central and peripheral clocks in regulating energy homeostasis. The circadian system has been shown to regulate rhythmic insulin secretion from the pancreas via both neural signals and hormonal levels (e.g., cortisol and norepinephrine), as well as via cell autonomous clock regulation within the pancreatic β-cell itself. An early observation was that whole-body mutant *Clock*$^{\Delta 19/\Delta 19}$ mice developed obesity without displaying hyperinsulinemia, a phenomenon that indicated concurrent β-cell failure. This was later confirmed using pancreas- and β-cell–specific *Bmal1*-deficient mice, which exhibited glucose intolerance, hypoinsulinemia, and impaired glucose-stimulated insulin secretion. The molecular clock within other peripheral tissues such as liver, adipose tissue, and skeletal muscle also regulate circadian fluctuations in insulin sensitivity and glucose disposal, which are highest in the morning and decline towards the evening. Liver-specific *Bmal1* mutant studies have revealed liver clock promotion of gluconeogenesis, glycogenolysis, and mitochondrial oxidative metabolism in the sleep/fasting period while promoting glycogen synthesis in the wake/feeding period. Muscle-specific *Bmal1* deficient mice display reduced glucose tolerance, concomitant with lower levels of proteins involved in glucose uptake by muscle cells (e.g., the glucose transporter GLUT4). Ablation of the *Cry1* and *Cry2* repressors in the negative limb of the clock alters glucagon and glucocorticoid signaling in the liver, contributing to hyperglycemia and impaired glucose tolerance in these mutant mice. Together, these genetic studies in mice suggest a role for tissue-specific clocks in the partitioning of energy utilization across the sleep-wake cycle.

Importantly, peripheral clocks also interact with other environmental factors such as diet and time of feeding. For example, high-fat feeding leads not only to obesity and metabolic syndrome in mice, but also to perturbed clock gene expression across multiple peripheral tissues and a disrupted sleep-wake/fasting-feeding cycle, as revealed by increased activity and feeding during the daytime. Furthermore, mice that are fed a high-fat diet exclusively during the light phase gain significantly more weight than mice that are fed the same diet during the dark period—the active period for mice. Additionally, the metabolic phenotypes arising from ad lib high-fat feeding can be significantly ameliorated by restricting the time of high-fat feeding exclusively to the dark period. Time-restricted feeding can also increase the activity of brown adipose tissue in mice and reduce hepatic glucose production to instead promote beta oxidation of fatty acids. These findings have been corroborated in human interventional studies, which have demonstrated that time-restricted feeding can improve metabolic homeostasis and promote weight loss. Time-restricted feeding may also modulate central regulation of sleep and hunger, as a study found that humans who restricted their food intake to a shorter than ad lib period also consumed less daily calories and reported improved sleep.

Finally, animal studies have further shown that when the light-dark cycle is disrupted or animals are subjected to conditions mimicking "jetlag"—by artificially advancing or delaying the daily light period—there is desynchronization amongst circadian clocks and subsequent weight gain. Accumulating evidence in humans suggests that circadian misalignment both disrupts and desynchronizes circadian clocks across tissues. Prolonged circadian misalignment using forced desynchrony protocols reduces insulin sensitivity in the pre- and postprandial state. Under such conditions, insulin secretion fails to suppress glucose levels, suggesting inadequate β-cell compensation. Moreover, resting metabolic rate declines significantly both in the awake and sleeping state, altogether providing potential explanations why shift work can increase the risk of obesity, type 2 diabetes, and the metabolic syndrome.

Human genetic association studies also support a role for clock genes in metabolic homeostasis and beta cell function. Carriers of a certain *BMAL1* polymorphism have a greater risk of developing type 2 diabetes, while *CLOCK* variants have been found to interact with diet, such that variants can have a protective effect on insulin sensitivity in individuals with high monounsaturated fat intake or in individuals provided a low-fat diet. Instead, the minor allele of another *CLOCK* gene variant has been associated with increased waist circumference, but only in those with high saturated fat intake. Similarly, *NPAS2* and *BMAL1* variants have been associated with a greater risk of hypertension. Melatonin receptor *MTNR1B* gene variants, which result in increased expression of MTNR1B, have been associated with elevated fasting blood glucose levels and reduced insulin secretion irrespective of their level of glycemic control, consistent with the known effect of melatonin on insulin secretion and lower insulin secretion in the evening. These association studies highlight the role of the circadian system in metabolism, as well as potential for interactions of external perturbations—such as circadian misalignment—with a protective or adverse genetic profile.

A large proportion of society recurrently shifts sleep-wake times between working/non-free days and free days. This social jetlag has been increasingly tied to metabolic disruptions, including a greater risk of obesity and type 2 diabetes. As this involves recurrent phase advances and phase delays—like shift work but of smaller magnitude—it is possible that social jetlag also results in perturbed energy expenditure, in combination with disruptions to the circadian rhythm of hunger drive, further increasing the risk of obesity. Repeated shifts in the food- and SCN-driven rhythm of insulin release may similarly over time increase the risk of type 2 diabetes. Shifted feeding rhythms in relation to the sleep-wake cycle and the timing of SCN activity may be causally involved in this pathogenesis. This is exemplified by the disorders known as night-eating syndrome and sleep-related eating disorder. In the former syndrome, a large part of daily calorie consumption occurs in the evening and nighttime hours, and this shifted meal pattern has been associated with a delayed timing of the internal clock. Some evidence exists that these syndromes are associated with obesity. Individuals who report sleeping fewer hours or who are subjected to restricted sleep for a few consecutive days have also been found to consume more calories later in the evening, perhaps explaining why sleep restriction increases the risk of obesity. These associations have also been observed in individuals with later onset of sleep, i.e., evening chronotypes. Night-eating syndrome and later chronotypes have also been linked to type 2 diabetes and may be more common than other eating disorders such as binge-eating disorder. Both conditions have also been found to be associated with impaired glycemic control—such as a greater likelihood of hemoglobin A1c values exceeding 7%—in patients already suffering from type 2 diabetes, emphasizing how proper alignment of internal circadian rhythms with external factors are key contributing factors for long-term metabolic homeostasis.

Circadian Clocks in Relation to Brain Health and Cognition

Molecular circadian clocks are present not only within the extra-SCN regions of the brain but also in neurons, astrocytes, and microglia. Emphasizing the functional significance of properly aligned clocks for brain health, shift workers have been found to have decreased grey matter in brain regions involved in memory and executive functions, with more notable effects in individuals who had shorter recovery periods between the onset of each shift work cycle. Adults performing rotating shift work for many years have also been shown to exhibit signs of accelerated cognitive aging. Notably, evidence suggests that these effects may be reversible, as those who have stopped carrying out shift work exhibit normal cognitive performance 5 or more years later.

Recent studies have also uncovered an important role for perturbed circadian and sleep-wake rhythms in neurodegenerative conditions such as Alzheimer's disease (AD), Huntington disease (HD), and Parkinson's disease (PD). Amyloid beta, a key pathognomonic component

of AD, normally exhibits circadian fluctuations in the extracellular space in the brain, as well as in the cerebrospinal fluid and plasma in humans, peaking during the active period and falling during sleep. Of note, these daily rhythms of amyloid beta accumulation are dampened in mice that are prone to develop AD; reduced fluctuations in plasma amyloid beta fluctuations have also been noted in older compared with younger individuals. It is believed that removal of amyloid beta (and other neurotoxic substances) during the nighttime sleep period is facilitated by a lymphatic-like system that relies on glial cells (the "glymphatic" system). Whereas the function of this system has been shown to be important in mice, its circadian components and relevance to humans remain to be determined. Consistent with a role for circadian rhythms in the pathogenesis of AD, ablation of core clock genes throughout the brain or within subregions of the brain increases oxidative stress and neuronal cell death, while promoting scarring of brain tissue (astrogliosis). Furthermore, perturbed light-dark cycles increased pathology associated with oxidative stress, and single-nucleotide polymorphisms in *Clock* and *Bmal1* have been associated with increased risk of developing AD.

Evidence also indicates that the relationship between the circadian/sleep-wake system and AD is bidirectional. For example, patients suffering from AD exhibit several signs of perturbed circadian rhythms, the most prominent of such phenomena being "sundowning," whereby AD patients become more agitated and exhibit delirium-like symptoms in the afternoon or evening. Studies have furthermore indicated that in severe forms of AD, the circadian rhythm is phase delayed. Aged AD-prone mice also display perturbed sleep-wake patterns, which can be corrected by immunization against amyloid beta or by an orexin antagonist. Further research will help uncover the primary pathogenic contribution of the circadian system, and its independent contribution from perturbed sleep, in conditions like AD. Notably, evidence suggests that interventions that increase daytime light exposure and include melatonin supplementation are able to ameliorate symptoms of AD, presumably by counteracting disrupted circadian rhythms.

While the relation between shift work and depression has not been extensively studied, disruption of sleep and circadian rhythms and the pathogenesis of depression are intimately interlocked. Clock genes have also been implicated in depression and mood both in animal and human studies. Polymorphisms of genes that regulate sleep and circadian rhythms—for instance, a long gene variant of *PER3*—have also been linked to bipolar disorder and schizophrenia, while *CRY2* and *CLOCK* gene polymorphisms are associated with seasonal affective disorder, a type of depression arising in the fall and winter months when the levels of sunlight are lowest. Bipolar disorder is furthermore often triggered by circadian disruptions or curtailed sleep. Both bipolar disorder and schizophrenia have been linked to various forms of circadian disruption following disease onset, and a critical component of disease treatment often involves normalizing sleep and sleep-wake rhythms.

Sleep deprivation by itself is known to reduce alertness, impair decision-making, and increase risk for accidents—after 18–24 h of continuous wakefulness, several skills exhibit the same degree of decline as following mild alcohol intoxication. However, cognitive abilities may suffer even further when sleep restriction is combined with circadian misalignment as in shift work. In one study, participants were subjected to ~33-h long days in parallel with reduced sleep (equivalent to 5.6 h sleep in a 24-h period), yielding a forced desynchrony protocol coupled with sleep loss. When subjects were tested at the nadir of their circadian period, the subjects' reaction speed dropped almost by an order of magnitude compared with controls. In another study, researchers noted almost a 36% greater incidence of serious medical errors in resident interns who regularly worked 24-h or longer shifts compared with those who were randomly assigned to work up to 16-h long shifts. Furthermore, errors that resulted in patient death were three times more likely to occur in residents working extended hours compared with those who only worked up to 16-h long shifts.

Circadian Regulation of Gastrointestinal Homeostasis and the Microbiota Physiologic aspects of the gastrointestinal (GI) tract exhibit day-night variations that anticipate and prepare for food intake and digestion during the active period. Gastric emptying, as well as colonic motility, are considerably greater during the active phase, as the phasic motor program supporting movement of digested material along the intestine is approximately twice as fast during the day compared with night. Bile acid secretion also exhibits circadian rhythmicity in the intestine, as does absorption and the expression of many nutrient uptake transporters in the intestinal wall, including the main glucose transporter protein SGLT1. The permeability of the intestinal wall also varies throughout the sleep-wake cycle, and mice exposed to chronic sleep fragmentation exhibit increased intestinal permeability, which may enable inflammatory molecules from bacteria to reach the systemic circulation.

The composition and function of the microbe population living in the intestine (i.e., the gut microbiota) also display circadian rhythmicity, orchestrated by both host circadian clock gene expression and food intake rhythms. Accordingly, circadian disruption, either by environmental or genetic means, perturbs these microbial rhythms, disrupting both bacterial levels and the metabolic functions of the gut microbiota. For example, alterations in the expression and functions of the gut microbiota have been noted in humans exposed to acute jetlag, and evidence suggests that curtailing sleep, which often accompanies shift work and jetlag, can alter the gut microbiota. By increasing local and systemic inflammation, circadian disruption of the gut microbiota may be causally involved in the increased risk of inflammatory bowel disease (Crohn's disease and ulcerative colitis) and colon cancer in shift workers. Gender-specific differences have also been reported, as female mice display more pronounced microbial rhythms. Interestingly, the gut microbiome has also been shown to influence the rhythms of host tissues, such as the intestine and liver, suggesting that a bidirectional relationship exists between tissues that regulate metabolic processes and the gut microbiome across the sleep-wake cycle. These findings may furthermore have clinical implications, given that the gut microbiome may both directly (in the gut lumen) and indirectly (through host-microbiota interactions) impact pharmacokinetic and pharmacodynamic properties of therapeutic drugs across the 24-h day-night cycle.

Cardiovascular Health and the Circadian Clock An early epidemiologic observation was a greater incidence of myocardial infarction in the morning hours, with the lowest risk during the period preceding sleep. Other cardiovascular outcomes such as sudden cardiac death and syncope also exhibit a daily peak in the morning. Blood pressure (BP) typically peaks around 21:00 h and decreases later during sleep, partially due to a circadian nighttime dip of around 3–6 mmHg in systolic BP and 2–3 mmHg in diastolic BP. A dip in blood pressure of either less than 10% or greater than 20% during normal sleep has been associated with worse cardiovascular prognosis. Heart rate also typically decreases during sleep, while mistimed sleep leads to higher heart rate during their sleep time. Thus, a combination of reasons—which may also involve altered glucocorticoid levels and increased platelet aggregation—may contribute to a greater risk of cardiovascular disease in the morning. Subsequent epidemiologic studies also have demonstrated that shift work increases the risk of dyslipidemia and hypertension, as well as the risk of coronary heart disease, including myocardial infarction. These findings are in line with interventional findings in which circadian misalignment has been induced either by inverting the sleep-wake cycle or by imposing 28-h days on healthy human subjects. These studies have found that circadian misalignment elevates 24-h blood pressure, particularly during sleep. These changes may be causally related to how the autonomic system is regulated during sleep, as evidenced by reduced vagal cardiac control when the sleep-wake cycle is inverted.

Circadian Disruption and Cancer In 2007, the International Agency for Research on Cancer declared that shift work that involves circadian disruption is likely carcinogenic to humans. While evidence for an association between shift work and general cancer incidence is mixed, accruing evidence supports a link between shift work and

increased risk of developing colon and breast cancer, as well as having a poorer cancer prognosis. Telomere shortening, a phenomenon in aging that destabilizes the genome, has also been observed in shift workers as well as in individuals suffering from short sleep. This may reduce the ability of damaged or senescent cells to undergo apoptosis, and instead lead to uninhibited cell growth and cancer. An indirect role for the circadian clock has also come from retrospective studies on how cancer risk is related to food timing and duration of the nighttime fast in humans. These studies indicate that by portioning food intake to a restricted period of the day, circadian processes are optimized in a way that confers reduced risk of carcinogenic cell damage. Studies of recurring fasting have also been shown to lower the risk as well as to delay the onset of cancer.

Experimental genetic evidence has also implicated clock disruption as a factor in tumorigenesis. Genetic loss of *Per2* or *Bmal1* has been shown to promote lung tumorigenesis, while studies in *Per2* mutant mice have also revealed increased radiation-induced lymphoma associated with dysregulation of the cell cycle. However, disruption of the *Cry* gene in mice has also been implicated in tumor protection due to increased susceptibility to cell death. Thus, while both epidemiologic and experimental evidence suggests a link between circadian disruption and cancer, a full understanding of the role of circadian systems in tumorigenesis remains an area for investigation.

Circadian Regulation of the Immune System Circadian misalignment and sleep restriction both alter population levels of immune cells and decrease the ability of immune cells to produce reactive radicals. Chronic circadian disruption may thereby impair the immune system's ability to conduct immunosurveillance at the proper time of day and reduce the ability to mount an appropriate response upon exposure of pathogens during the recovery/sleep phase, when the immune system is typically more active. Instead, circadian misalignment increases a range of clinically used inflammatory markers (e.g., C-reactive protein, tumor necrosis factor α, and interleukin 6), and such changes have been noted even when the sleep-wake cycle is only prolonged to a slightly longer than normal 24.6-h day. While similar effects are also observed following acute total sleep deprivation or recurrent partial sleep restriction, circadian misalignment has been found to promote an even more pronounced elevation of such markers. Genetic clock disruption in peritoneal macrophages has also revealed clock control of Toll-like receptor 9, which is responsible for identifying molecules from foreign pathogens. *Clock* knockout mice also have reduced T cell antigen response, and mice immunized during the day had a stronger T cell response than mice immunized at night, supporting regulation of the immune system by the clock.

Aging and the Circadian Clock Instability in the clock system is an often overlooked hallmark of aging. Aging is associated with a decline in the robustness of intrinsic rhythmic processes at the behavioral, physiologic, and molecular levels in both human and animal models. At the *behavioral* level, aging leads to reduced and fragmented sleep, dampened locomotor activity and feeding rhythms, and a reduced ability to entrain to light, as old rodents are 20 times less sensitive to the entraining effects of light relative to young animals. Even middle-aged individuals exposed to jetlag also exhibit more symptoms of circadian misalignment, such as more time awake and reduced alertness, compared with young individuals. On a *physiologic* level, some of the hallmarks of aging are a reduction in amplitude (e.g., flattening of circadian pattern) and a phase-advance (e.g., a shift in the timing of the peak or nadir) in rhythms of the endocrine and neuroendocrine systems, including sleep onset and offset. For example, cortisol, DHEA, and melatonin all have dampened rhythms and are phase-advanced in aging; the combination of such changes may, for instance, contribute to more fragmented sleep and lower levels of restorative slow-wave sleep in aged individuals. Aging also leads to alterations in peptide expression in the SCN (VIP and AVP) and reduced amplitude of rhythms of SCN electrical activity. Further, while the SCN-dependent body temperature rhythm—a generally accepted marker for the integrity of circadian rhythms—peaks in the evening and is lowest in the early morning in young individuals, aged healthy subjects display a phase advance and decrease in circadian amplitude in body temperature rhythms. Indeed, evidence suggests that internal desynchrony between core body temperature rhythms and the sleep-wake cycle may contribute to age-associated circadian alterations. On a *molecular* level, aging is associated with decreased expression and altered diurnal profiles of several of the core clock genes, including *Clock* and *Bmal1*, within both SCN and peripheral tissues such as heart and liver. Interestingly, the acute induction of *Per1* in response to light was markedly reduced in the SCN of aged mice compared with young mice, potentially contributing to their delayed response to light entrainment. Mice lacking *Bmal1* die prematurely compared with control mice, consistent with premature accumulation of reactive oxygen species. These mice have an accelerated onset of numerous age-related pathologies, including cataracts, sarcopenia, reduced organ size, and decreased hair growth. Instead, deficiency of *Cryptochrome*, a repressor of the internal clock repressor, has been associated with alterations in liver regeneration, while BMAL1 and PER2 may be important for proper neurogenesis in the hippocampus, a brain region in which adult mammals normally exhibit continuous cell division. Altogether, this suggests that the highly conserved circadian clock is important for regulating a wide range of homeostatic processes, including cell-cycle pathways, that when properly phased to each other promote organismal fitness.

Measurements of altered circadian rhythms with age may serve as a useful biomarker for aging. An intriguing question is whether the decline in amplitude of rhythms correlates with a decline in function, and importantly whether restoration of these rhythms with age, through either behavioral or pharmacologic intervention, would delay the aging process. Of note, transplantation of the SCN from a young rat into an old rat "rescued" the rhythms of both locomotor activity and corticotropin hormone (CRH), suggesting that the SCN is an important target for age-related changes in clocks. Treatments targeting the SCN may therefore ameliorate some of the deterioration in aged individuals.

CHRONOTHERAPY AND FUTURE DIRECTIONS

Chronopharmacology, the study of how the timing of drug administration may impact its effectiveness, is a rapidly emerging field. Since physiologic processes vary across the day, the timing of administration of medication may help optimize patient care. For example, since endogenous cholesterol synthesis is rhythmic in liver and peaks during the early morning hours, administration of statins (HMG-CoA reductase inhibitors) in the evening prior to bedtime has proven to be more effective than daytime administration at reducing low-density lipoprotein cholesterol (LDL-C) levels because the highest concentration of the medications coincides with the peak in the rhythmic endogenous cholesterol production. Given that blood pressure exhibits a 24-h rhythm—being lowest during sleep—angiotensin-converting enzyme (ACE) inhibitors have been shown to be most effective at night to normalize the blood pressure rhythms, restoring the nighttime dip in blood pressure. Administration of cancer treatments according to circadian rhythms has also been shown to increase chemotherapy effectiveness while decreasing toxicity in a wide range of drugs. For example, 5-FU works best to treat colorectal cancer when administered at night, a time when the cancerous cells are more vulnerable while normal cells are quiescent and therefore less sensitive. Doxorubicin administration early in the morning to treat ovarian cancer has also been shown to be less toxic, as white blood cells recover faster than if the drug is given in the evening. Finally, the more severe morning symptoms of rheumatoid arthritis are linked to increased inflammation during the evening; therefore, prevention of the night-time upregulation of the immune/inflammatory reaction is more effective when glucocorticoids are administered with a night-time release formulation.

Recognition of circadian rhythms is also critical for diagnoses and treatment of endocrine disorders. The diagnosis of Cushing's syndrome, which is characterized by hypercortisolemia, might be missed if the patient's cortisol levels were measured in the morning, as endogenous cortisol production is typically highest during morning

and lowest at night; therefore, clinical diagnosis requires cortisol to be measured in the late evening when the levels of this hormone should typically be low. On the other hand, adrenal insufficiency is diagnosed by measuring cortisol in the morning when at its physiologic peak, and glucocorticoid therapy for these patients aims to mimic the endogenous rhythms of cortisol, as short-acting synthetic glucocorticoids are usually given several times a day in tapering doses, such that the largest amount is taken in the morning and the smallest in the evening. Diabetes is another endocrine disorder intimately tied to circadian rhythms. Oral glucose tolerance has repeatedly been shown to be impaired in the afternoon and evening compared to the morning, likely due to a combination of a circadian regulation of insulin sensitivity within peripheral tissues and reduced insulin secretion during the night. Similarly, due to a surge in hormone levels in the morning, diabetes patients may suffer from the dawn phenomenon (or dawn effect), an abnormally high morning increase in blood glucose due to impaired response in insulin secretion. A related phenomenon that can be tied to evening timing of insulin doses is the "rebound" or Somogyi effect. In this scenario, the initially noted clinical sign, in the form of elevated glucose levels, may be noted in the morning. However, the underlying cause is hypoglycemia occurring during the night, which produces a counterregulatory hormonal response that subsequently results in morning hyperglycemia. As patients with type 2 diabetes often lack these daily cycles of insulin secretion and glucose tolerance, this further highlights that time of day is an important consideration for the diagnosis and treatment of metabolic disorders such as type 2 diabetes.

As our knowledge of the complexity of the interaction between circadian and physiologic processes deepens, further advances to rationally develop new strategies for treatments of disorders affected by circadian misalignment are essential. For example, novel compounds have begun to emerge from unbiased drug discovery screens that impact circadian clock components, either shortening or lengthening the period, including CRY stabilizers or various inhibitors of CKIδ, CKIε, and GSK-3. Pharmacologic control of the circadian cycle may be useful in the treatment of circadian disorders and metabolic disturbances with a circadian component. Understanding how the circadian clock controls biological functions will shed new light onto the pathogenesis of metabolic disorders with a circadian component, such as type 2 diabetes and metabolic syndrome, and will yield insight into how timing of drug delivery will impact patient care.

476 Network Medicine: Systems Biology in Health and Disease

Joseph Loscalzo

The field of human biology has progressed over the last three centuries largely as a result of the reductionist approach to the scientific problems that challenge the discipline. Biologists study the experimental response of a variable of interest in a cell or organism while holding all other variables constant. In this way, it is possible to dissect the individual components of a biologic system and assume that a thorough understanding of a specific component (e.g., an enzyme or a transcription factor) will provide sufficient insight to explain the global behavior of that system (e.g., a metabolic pathway or a gene network, respectively). Biologic systems are, however, much more complex than this approach assumes and manifest behaviors that frequently (if not invariably) cannot be predicted from knowledge of their component parts characterized in isolation. Growing recognition of this shortcoming of conventional biologic research has led to the development of a new discipline, *systems biology, which is defined as the holistic study of living organisms or their cellular or molecular network components to predict their response to perturbations*. Concepts of systems biology can be applied readily to human disease and therapy and define the field of *systems pathobiology*, in which genetic or environmental perturbations produce disease and drug perturbations restore normal system behavior.

Systems biology evolved from the field of systems engineering in which a linked collection of component parts constitute a network whose output the engineer wishes to predict. The simple example of an electronic circuit can be used to illustrate some basic systems engineering concepts. All the individual elements of the circuit—resistors, capacitors, transistors—have well-defined properties that can be characterized precisely. However, they can be linked (wired or configured) in a variety of ways, each of which yields a circuit whose response to voltage applied across it is different from the response of every other configuration. To predict the circuit's (i.e., system's) behavior, the engineer must study its response to perturbation (e.g., voltage applied across it) holistically rather than its individual components' responses to that perturbation. Viewed another way, the resulting behavior of the system is greater than (or different from) the simple sum of its parts, and systems engineering utilizes rigorous mathematical approaches to predict these complex, often nonlinear, responses. By analogy to biologic systems, one can reason that detailed knowledge of a single enzyme in a metabolic pathway or of a single transcription factor in a gene network will not provide sufficient detail in context to predict the output of that metabolic pathway or transcriptional network, respectively. Only a systems-based approach will suffice.

It has taken biologists a long time to appreciate the importance of systems approaches to biomedical problems. Reductionism has reigned supreme for many decades, largely because it is experimentally and analytically simpler than holism, and because it has provided insights into biologic mechanisms and disease pathogenesis that have led to successful therapies. However, reductionism cannot solve all biomedical problems. For example, the so-called off-target effects of new drugs that frequently limit their adoption likely reflect the failure of a drug to be studied in holistic context, that is, the failure to explore all possible actions aside from the principal target action for which it was developed. Other approaches to understanding biology are, therefore, clearly needed. With the growing body of genomic, proteomic, and metabolomic data sets in which dynamic changes in the expression of many genes and many metabolites are recorded after a perturbation and with the growth of rigorous mathematical approaches to analyzing those changes, the stage has been set for applying systems engineering principles to modern biology.

Physiologists historically have had more of a (bio)engineering perspective on the conduct of their studies and have been among the first systems biologists. Yet, with few exceptions, they, too, have focused on comparatively simple physiologic systems that are tractable using conventional reductionist approaches. Efforts at integrative modeling of human physiologic systems, as first attempted by Guyton for blood pressure regulation, represent one application of systems engineering to human biology. These dynamic physiologic models often focus on the acute response of a measurable physiologic parameter to a system perturbation, and do so from a classic analytic perspective in which all the conventional physiologic determinants of the output parameter are known and can be modeled quantitatively.

Until recently, molecular systems analysis has been limited owing to inadequate knowledge of the molecular determinants of a biologic system of interest. Although biochemists have approached metabolic pathways from a systems perspective for over 50 years, their efforts have been limited by the inadequacy of key information for each enzyme (K_M, k_{cat}, and concentration) and substrate (concentration) in the pathway. With increasingly rich molecular data sets available for systems-based analyses, including genomic, transcriptomic, proteomic, and metabolomic data, molecular biologists and biochemists are now poised to use systems biology approaches to explore biologic and pathobiologic phenomena.

PROPERTIES OF COMPLEX BIOLOGIC SYSTEMS

To understand how best to apply the principles of systems biology to human biomedicine, it is necessary to review briefly the building blocks of any biologic system and the determinants of system complexity. All systems can be analyzed by defining their static topology (architecture) and their dynamic (i.e., time-dependent) response to perturbation. In the discussion that follows, system properties are described that derive from the consequences of topology (form) or dynamic response (function). Any system of interacting elements can be represented schematically as a *network* in which the individual elements are depicted as nodes and their connections are depicted as links. The nature of the links among nodes reflects the degree of complexity of the system. *Simple systems* are those in which the nodes are linearly linked with occasional feedback or feedforward loops modulating system throughput in highly predictable ways. By contrast, *complex systems* are nodes that are linked in more complicated, nonlinear networks; the behavior of these systems by definition is inherently more difficult to predict owing to the nature of the interacting links, the dependence of the system's behavior on its initial conditions, and the inability to measure the overall state of the system at any specific time with great precision. Complex systems can be depicted as a network of lower-complexity interacting components or modules, each of which can be reduced further to simpler analyzable canonical motifs (such as feedback and feedforward loops, or negative and positive autoregulation); however, a central property of complex systems is that simplifying their structures by identifying and characterizing the individual nodes and links or even simpler substructures does not necessarily yield a predictable understanding of a system's behavior. Thus, the functioning system is greater than (or different from) the sum of its individual, tractable parts.

Defined in this way, most biologic systems are complex systems that can be represented as networks whose behaviors are not readily predictable from simple reductionist principles. The nodes, for example, can be metabolites that are linked by the enzymes that cause their transformations, transcription factors that are linked by the genes whose expression they influence, or proteins in an interaction network that are linked by cofactors that facilitate interactions or by thermodynamic forces that facilitate their physical association. Biologic systems typically are organized as *scale-free*, rather than stochastic, networks of nodes. Scale-free networks are those in which a few nodes have many links to other nodes (highly linked nodes, or hubs), but most nodes have only a few links (weakly linked nodes). The term *scale-free* refers to the fact that the connectivity of nodes in the network is invariant with respect to the size of the network. This is quite different from two other common network architectures: random (Poisson) and exponential distributions. Scale-free networks can be mathematically described by a power law that defines the probability of the number of links per node ($P(k) = k^{-\gamma}$, where k is the number of links per node and γ is the slope of the log P(k) versus log(k) plot); this unique property of most biologic networks is a reflection of their self-similarity or fractal nature **(Fig. 476-1)**.

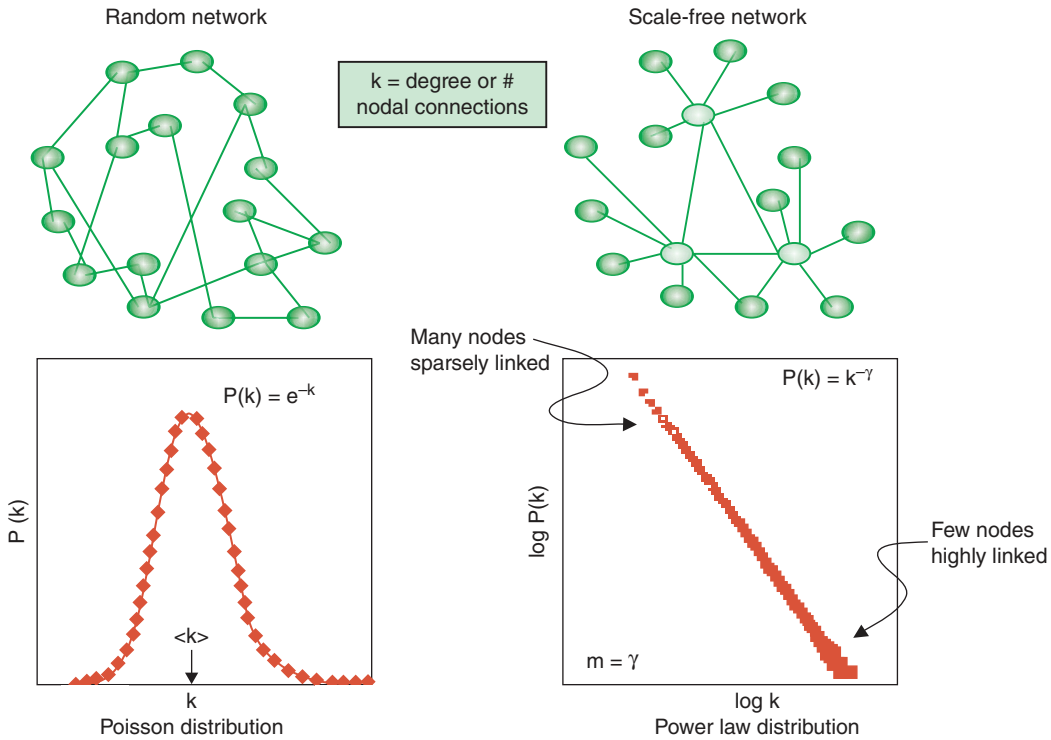

FIGURE 476-1 Network representations and their distributions. A random network is depicted on the left, and its Poisson distribution of the number of nodal connections (k) is shown in the graph below it. A scale-free network is depicted on the right, and its power law distribution of the number of nodal connections (k) is shown in the graph below it. Highly connected nodes (hubs) are lightly shaded.

There are unique properties of scale-free biologic systems that reflect their evolution and promote their adaptability and survival. Biologic networks likely evolved one node at a time in a process in which new nodes are more likely to link to a highly connected node than to a sparsely connected node. Furthermore, scale-free networks can become sparsely linked to one another, yielding more complex, *modular scale-free topologies*. This evolutionary growth of biologic networks has three important properties that affect system function and survival. First, this scale-free addition of new nodes promotes *system redundancy*, which minimizes the consequences of errors and accommodates adverse perturbations to the system robustly with minimal effects on critical functions (unless the highly connected nodes are the focus of the perturbation). Second, this resulting network redundancy provides a survival advantage to the system. In complex gene networks, for example, mutations or polymorphisms in weakly linked genes account for biodiversity and biologic variability without disrupting the critical functions of the system; only mutations in highly linked (*essential*) genes (hubs) can shut down the system and cause embryonic lethality. Third, scale-free biologic systems facilitate the flow of information (e.g., metabolite flux) across the system compared with randomly organized biologic systems; this so-called "small-world" property of the system (in which the clustered nature of the highly linked hubs defines a local neighborhood within the network that communicates through weaker, less frequent links to other clusters) minimizes the energy cost for the dynamic action of the system (e.g., minimizes the transition time between states in a metabolic network).

These basic organizing principles of complex biologic systems lead to three unique properties that require emphasis. First, biologic systems are *robust*, which means that they are quite stable in response to most changes in external conditions or internal modification. Second, a corollary to the property of robustness is that complex biologic systems are *sloppy*, which means that they are insensitive to changes in external conditions or internal modification except under certain uncommon conditions (i.e., when a hub is involved in the change). Third, complex biologic systems exhibit *emergent properties*, which means that they manifest behaviors that cannot be predicted from the reductionist principles used to characterize their component parts. Examples of emergent behavior in biologic systems include spontaneous, self-sustained oscillations in glycolysis; spiral and scroll waves of depolarization in cardiac tissue that cause reentrant arrhythmias; and self-organizing patterns in biochemical systems governed by diffusion and chemical reaction.

APPLICATIONS OF SYSTEMS BIOLOGY TO PATHOBIOLOGY

The principles of systems biology have been applied to complex pathologic processes with some early successes. The key to these applications is the identification of emergent properties of the system under study in order to define novel, otherwise unpredictable (i.e., from the reductionist perspective) methods for regulating the system's response. Systems biology approaches have been used to characterize epidemics and ways to control them, taking advantage of the scale-free properties of the network of infected individuals that constitute the epidemic. Through the use of a systems analysis of a neural protein-protein interaction network, unique disease-modifying proteins have been identified that are common to a wide range of cerebellar neurodegenerative disorders causing inherited ataxias. Systems analysis and disease network construction of a pulmonary arterial hypertension network led to the identification of a unique disease module involving a pathway governed by microRNA-21. Systems biology models have been used to dissect the dynamics of the inflammatory response using oscillatory changes in the transcription factor nuclear factor (NF) κB as the system output. Systems biology principles also have been used to predict the development of an idiotypy–anti-idiotypy antibody network, describe the dynamics of species growth in microbial biofilms, and analyze the innate immune response. In each of these examples, a systems (patho) biology approach provided insights into the behavior of these complex systems that could not have been recognized with conventional scientific reductionism.

A unique application of systems biology to biomedicine is in the area of drug development. Conventional drug development involves identifying a potential target protein and then designing or screening compounds to identify those that inhibit the function of that target. This reductionist analysis has identified many potential drug targets and drugs, yet only when a drug is tested in animal models or humans are the systems consequences of the drug's action revealed; not uncommonly, so-called off-target effects may become apparent and be sufficiently adverse for researchers to cease development of the agent. A good example of this problem is the unexpected outcomes of the vitamin B–based regimens for lowering homocysteine levels. In these trials, plasma homocysteine levels were reduced effectively; however, there was no effect of this reduction on clinical vascular endpoints. One explanation for this outcome is that one of the B vitamins in the regimen, folate, has a panoply of effects on cell proliferation and metabolism that probably offset its homocysteine-lowering benefits, promoting progressive atherosclerotic plaque growth and its consequences for clinical events. In addition to these types of unexpected outcomes exerted through pathways that were not considered *ab initio*, conventional approaches to drug development typically do not take into consideration the possibility of emergent behaviors of the organism or the metabolic pathway or the transcriptional network of interest. Thus, a systems-based analysis of potential drugs (drug-target network analysis) can benefit the development paradigm both by enhancing the likelihood that a compound of interest will not manifest unforeseen adverse effects and by promoting novel analytic methods for identifying unique control points or pathways in metabolic or genetic networks that would benefit from drug-based modulation, including drug combinations.

SYSTEMS PATHOBIOLOGY AND HUMAN DISEASE CLASSIFICATION: NETWORK MEDICINE

Perhaps most important, systems pathobiology can be used to revise and refine the definition of human disease. The classification of human disease used in this and all medical textbooks derives from the correlation between pathologic analysis and clinical syndromes that began in the nineteenth century. Although this approach has been very successful, serving as the basis for the development of many effective therapies, it has major shortcomings. Those shortcomings include a lack of sensitivity in defining preclinical disease, a primary focus on overtly manifest disease, failure to recognize different and potentially differentiable causes of common late-stage pathophenotypes, and a limited ability to incorporate the growing body of molecular and genetic determinants of pathophenotype into the conventional classification scheme.

Two examples will illustrate the weakness of simple correlation analyses grounded in the reductionist principle of simplification (Occam's razor) in defining human disease. Sickle cell anemia, the "classic" Mendelian disorder, is caused by a Val6Gln substitution in the β chain of hemoglobin. If conventional genetic teaching holds, this single mutation should lead to a single phenotype in patients who harbor it (genotype-phenotype correlation). This assumption is, however, false, as patients with sickle cell disease manifest a variety of pathophenotypes, including hemolytic anemia, stroke, acute chest syndrome, bony infarction, and painful crisis, as well as an overtly normal phenotype. The reasons for these different phenotypic presentations include the presence of disease-modifying genes or gene products (e.g., hemoglobin F, hemoglobin C, glucose-6-phosphate dehydrogenase), exposure to adverse environmental factors (e.g., hypoxia, dehydration), and the genetic and environmental determinants of common intermediate pathophenotypes or endophenotypes (i.e., variations in those generic pathologic mechanisms underlying all human disease—inflammation, thrombosis/hemorrhage, fibrosis, cell proliferation, apoptosis/necrosis, immune response).

A second example of note is familial pulmonary arterial hypertension. This disorder is associated with over 100 different mutations in three members of the transforming growth factor β (TGF-β) superfamily alone: bone morphogenetic protein receptor-2 (BMPR-2), activin

receptor-like kinase-1 (Alk-1), and endoglin. All these different genotypes are associated with a common pathophenotype, and each leads to that pathophenotype by molecular mechanisms that range from haploinsufficiency to dominant negative effects. As only approximately one-fourth of individuals in families that harbor these mutations manifest the pathophenotype, other disease-modifying genes (e.g., the serotonin receptor 5-HT2B, the serotonin transporter 5-HTT), genomic and environmental determinants of common intermediate pathophenotypes, and environmental exposures (e.g., hypoxia, infective agents [HIV], anorexigens) probably account for the incomplete penetrance of the disorder.

On the basis of these and many other related examples, one can approach human disease from a systems pathobiology perspective in which each "disease" can be depicted as a network that includes the following modules: the primary disease-determining elements of the genome (or proteome, if posttranslationally modified), the disease-modifying elements of the genome or proteome, environmental determinants, and genomic and environmental determinants of the generic intermediate pathophenotypes. **Figure 476-2** graphically depicts these genotype-phenotype relationships as modules for the six common disease types with specific examples for each type. **Figure 476-3** shows a network-based depiction of sickle cell disease using this kind of modular approach.

Goh and colleagues developed the concept of a human disease network **(Fig. 476-4)** in which they used a systems approach to characterize the disease-gene associations listed in the Online Mendelian Inheritance in Man database. Their analysis showed that genes linked to similar disorders are more likely to have products that physically associate and greater similarity between their transcription profiles than do genes not associated with similar disorders. In addition, proteins associated with the same pathophenotype are significantly more likely to interact with one another than with other proteins not associated with the pathophenotype. Finally, these authors showed that the great majority of disease-associated genes are not highly connected genes (i.e., not hubs) and are typically weakly linked nodes within the functional periphery of the network in which they operate.

This type of analysis validates the potential importance of defining disease on the basis of its systems pathobiologic determinants. Clearly, doing this will require a more careful dissection of the molecular elements in the relevant pathways (i.e., more precise molecular pathophenotyping), less reliance on overt manifestations of disease for their classification, and an understanding of the dynamics (not just the static architecture) of the pathobiologic networks that underlie pathophenotypes defined in this way. **Figure 476-5** illustrates the elements of a molecular network within which a disease module is contained. This network is first identified by determining the interactions (physical or regulatory) among the proteins or genes that comprise it (the "interactome"). These interactions then define a topologic module within which exist functional modules (pathways) and disease modules. One approach to constructing this module is illustrated in **Fig. 476-6**. Examples of the use of this approach in defining novel determinants of disease are given in **Table 476-1**.

As yet another potential consideration, one can argue that disease reflects the later-stage consequences of the predilection of an organ

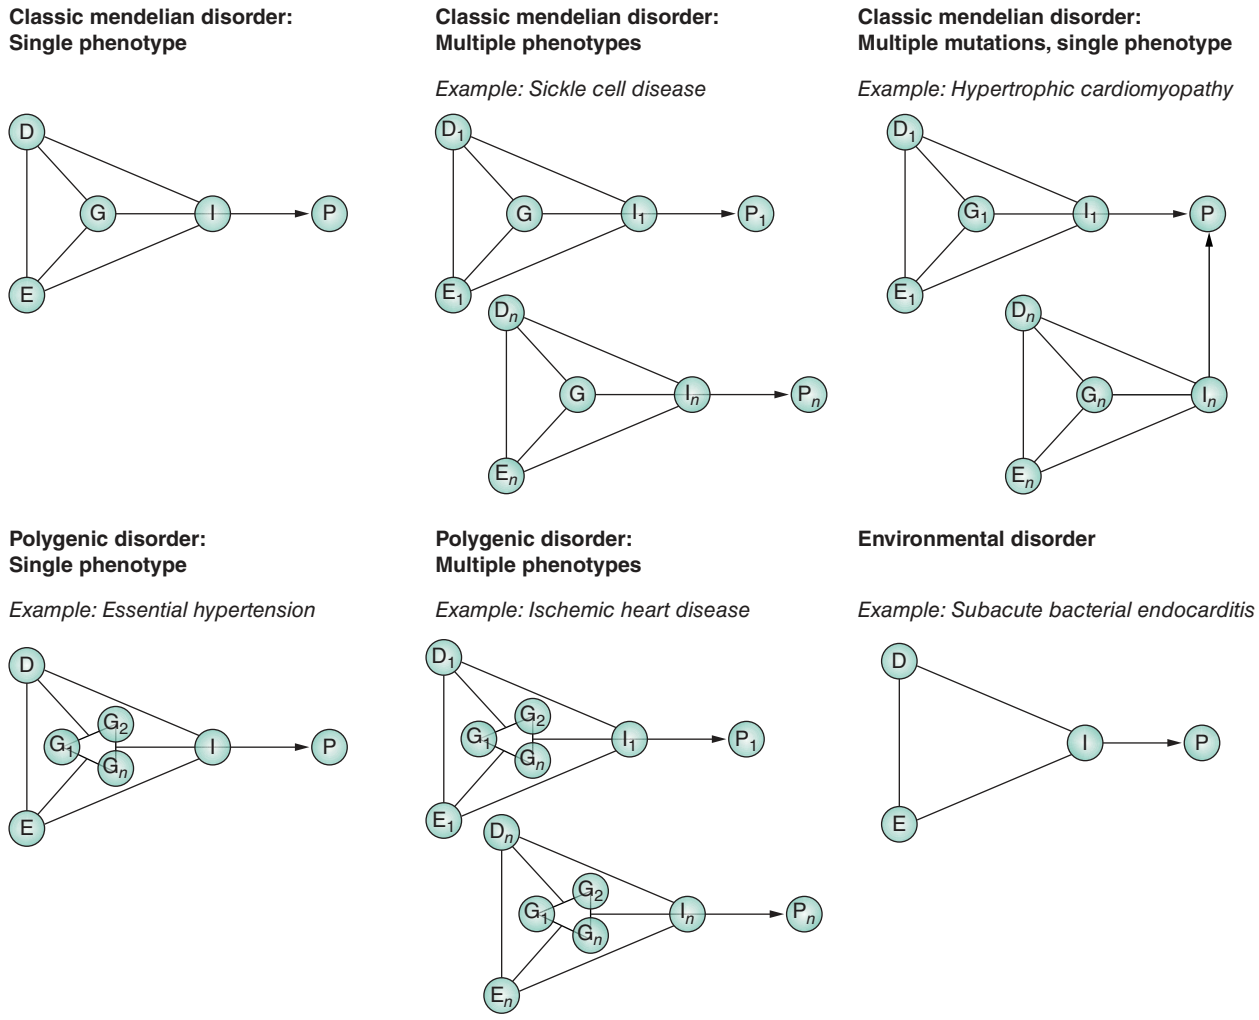

FIGURE 476-2 Examples of modular representations of human disease. system to manifest a particular intermediate pathophenotype in response to injury. This paradigm reflects a reverse causality view in which a disease is defined as a tendency to heightened inflammation, thrombosis, or fibrosis after an injurious perturbation. Where the process is manifest (i.e., the organ in which it occurs) is less important than that it occurs (with the exception of the organ-specific pathophysiologic consequences that may require acute attention). For example, from this perspective, acute myocardial infarction (AMI) and its consequences are a reflection of thrombosis (in the coronary artery), inflammation (in the acutely injured myocardium), and fibrosis (at the site or sites of cardiomyocyte death). In effect, the major therapies for AMI address these intermediate pathophenotypes (e.g., antithrombotics, statins) rather than any organ-specific disease-determining process. This paradigm would argue for a systems-based analysis that would first identify the intermediate pathophenotypes to which a person is predisposed, then determine how and when to intervene to attenuate that adverse predisposition, and finally limit the likelihood that a major organ-specific event will occur. Evidence for the validity of this approach is found in the work of Rzhetsky and colleagues, who reviewed 1.5 million patient records and 161 diseases and found that

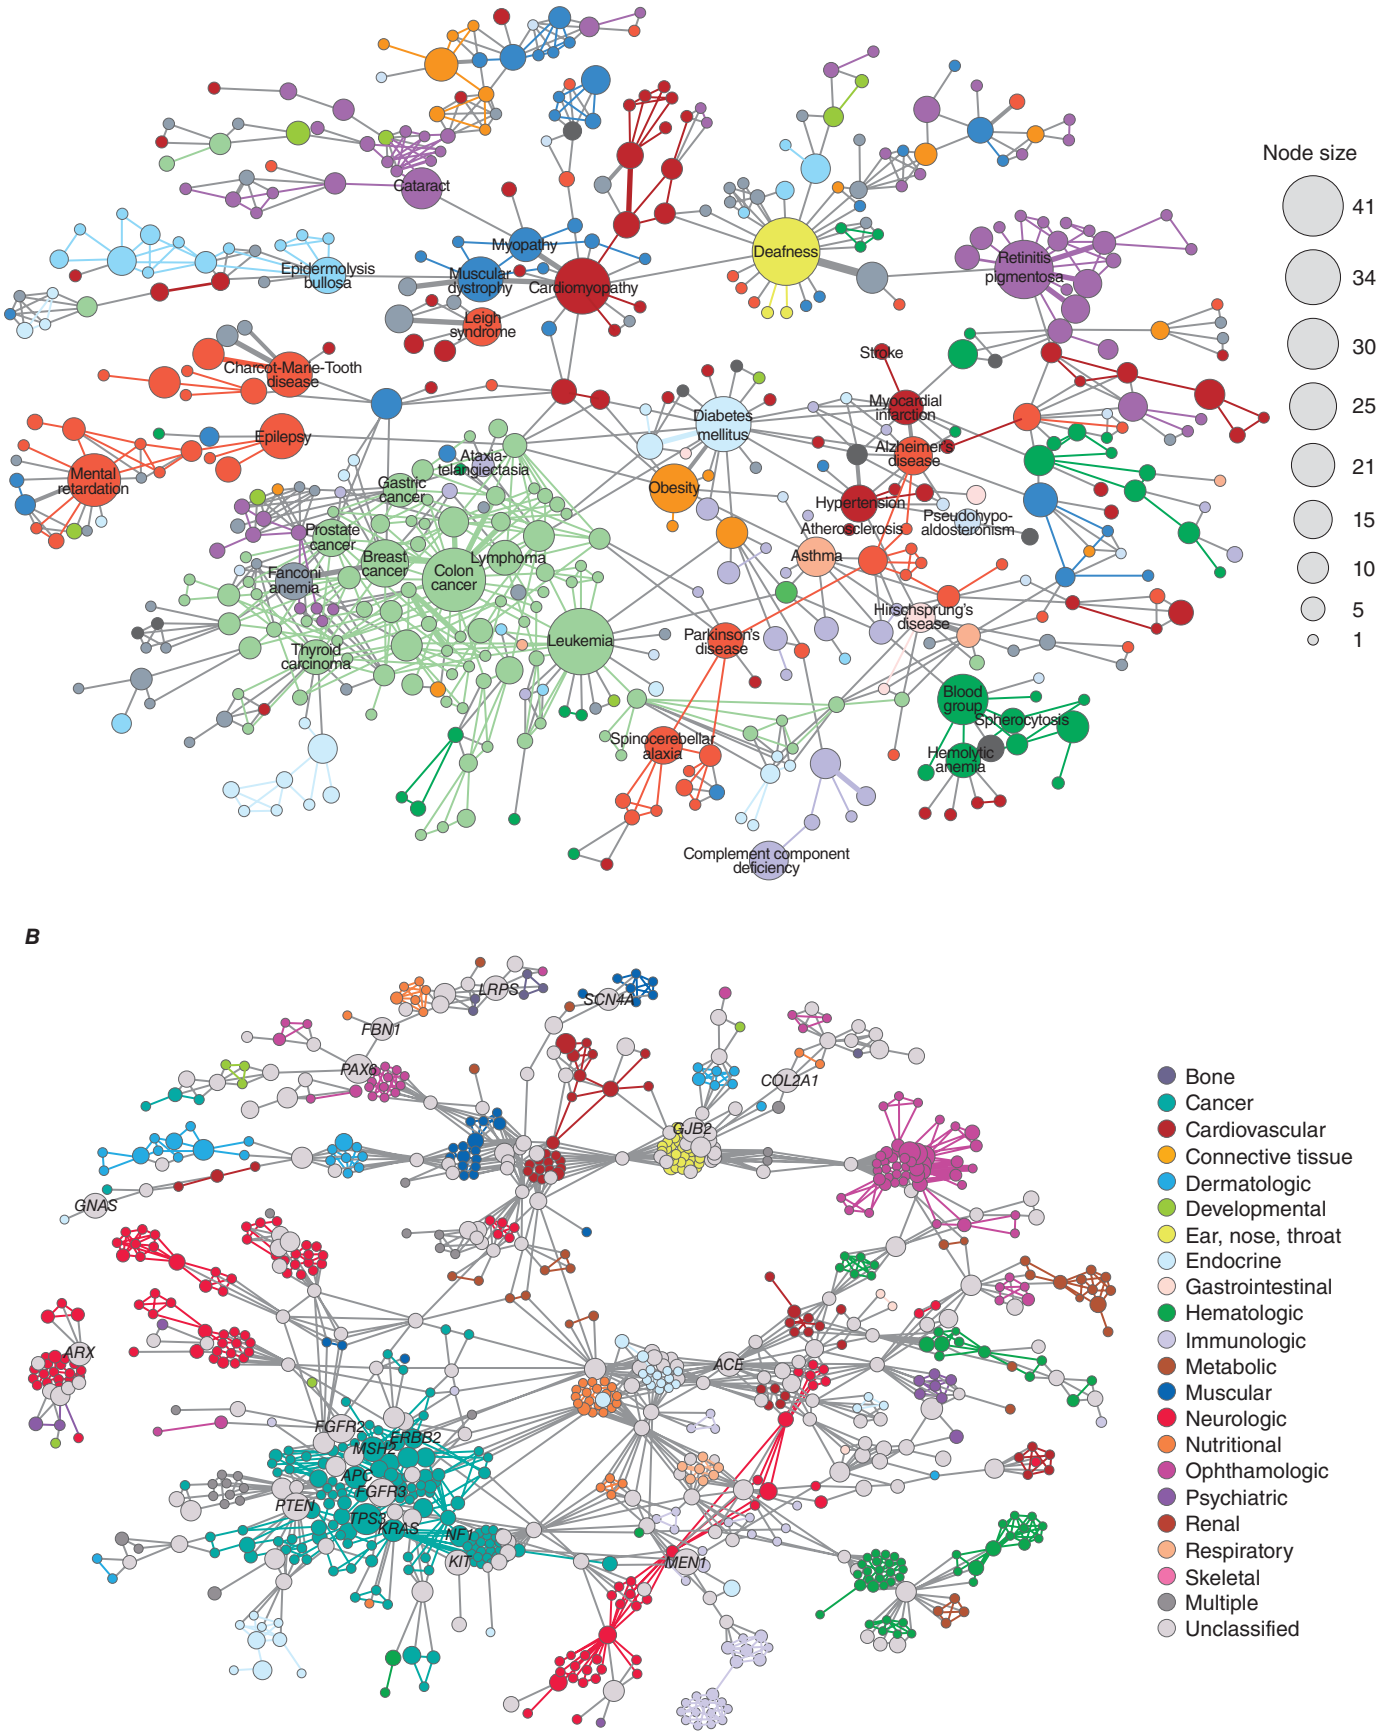

FIGURE 476-4 ***A.*** Human disease network. Each node corresponds to a specific disorder colored by class (22 classes, shown in the key to **B**). The size of each node is proportional to the number of genes contributing to the disorder. Edges between disorders in the same disorder class are colored with the same (lighter) color, and edges connecting different disorder classes are colored gray, with the thickness of the edge proportional to the number of genes shared by the disorders connected by it. ***B.*** Disease gene network. Each node is a single gene, and any two genes are connected if implicated in the same disorder. In this network map, the size of each node is proportional to the number of specific disorders in which the gene is implicated. *(Reproduced with permission from KI Goh et al: Proc Natl Acad Sci USA 104:8685, 2007.)*

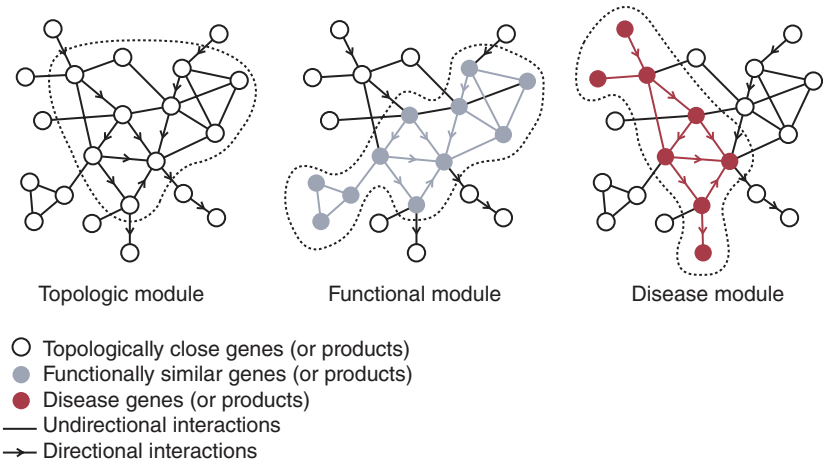

FIGURE 476-5 The elements of the interactome. The interactome includes topologic modules (genes or gene products that are closely associated with one another through direct interactions), functional modules (genes or gene products that work together to define a pathway), and disease modules (genes or gene products that interact to yield a pathophenotype). *(Reproduced with permission from AL Barabasi et al: Nat Rev Genet 12:56, 2011.)*

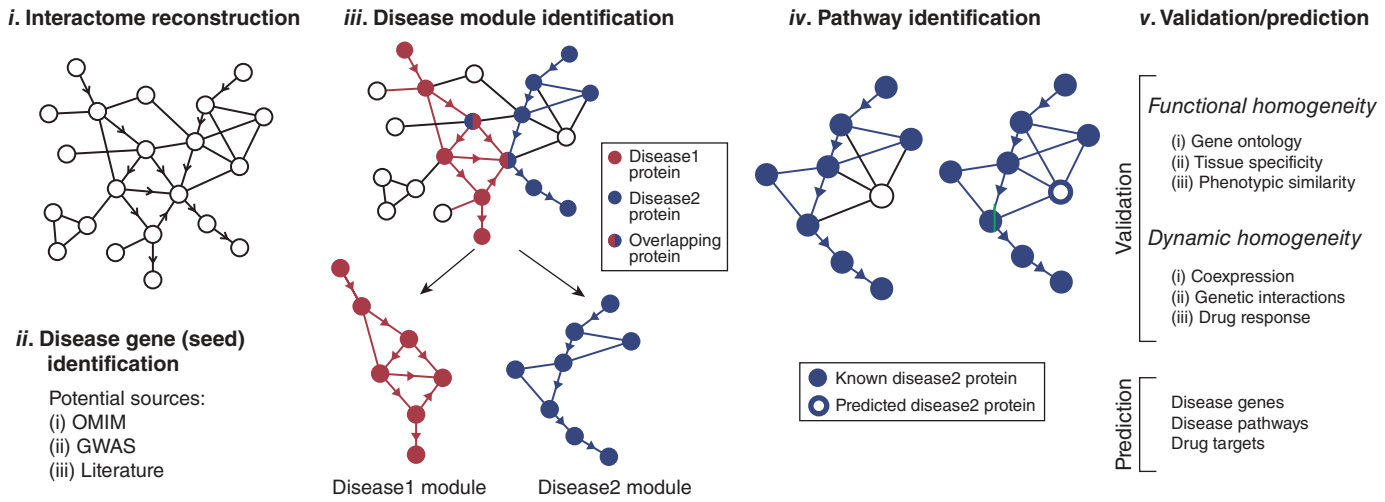

FIGURE 476-6 Approaches to identifying disease modules in molecular networks. A strategy for defining disease modules involves (i) reconstructing the interactome; (ii) ascertaining potential seed (disease) genes from the curated literature, the Online Mendelian Inheritance in Man (OMIM) database, or genomic analyses (genome-wide association studies [GWAS] or transcriptional profiling); (iii) identifying the disease module using different modeling or statistical approaches; (iv) identifying pathways and the role of disease genes or modules in those pathways; and (v) disease module validation and prediction. *(Reproduced with permission from AL Barabasi et al: Nat Rev Genet 12:56, 2011.)*

TABLE 476-1 Examples of Systems Biology Application to Disease

DISEASE	ANALYSIS	REFERENCE
Hereditary ataxias	Many ataxia-causing proteins share interacting partners that affect neurodegeneration	Lim et al: Cell 125:801–814, 2006
Diabetes mellitus	Metabolite-protein network analysis links three unique metabolite abnormalities in prediabetics to seven type 2 diabetes genes through four enzymes	Wang-Sattler et al: Mol Syst Biol 8:615, 2012
Ebstein-Barr virus infection	Viral proteome exerts its effects through linking to host interactome	Gulbahce et al: PLoS One 8:e1002531, 2012
Pulmonary arterial hypertension	Network analysis indicates adaptive role for microRNA 21 in suppressing rho kinase pathway	Parikh et al: Circulation 125:1520–1532, 2012

these disease phenotypes form a network of strong pairwise correlations. This result is consistent with the notion that underlying genetic predispositions to intermediate pathophenotypes form the predicate basis for conventionally defined end organ diseases.

Regardless of the specific nature of the systems pathobiologic approach used, these analyses will lead to a drastic revision of the way human disease is defined and treated, establishing the discipline of *network medicine, which reflects a fusion of the fields of systems biology and network science in the study of disease*. This will be a lengthy and complicated process, but ultimately will lead to better disease prevention and therapy and probably do so from an increasingly personalized perspective. The analysis of pathobiology from a systems-based perspective is likely to help define specific subsets of patients more likely to respond to particular interventions based on shared disease mechanisms. Although it is unlikely that the extreme of "individualized medicine" will ever be practical (or even desirable), complex diseases can be mechanistically subclassified and interventions may be tailored to those settings in which they are more likely to work. This approach serves as a basis for the development of precision medicine.

477 Emerging Neurotherapeutic Technologies

Jyoti Mishra, Karunesh Ganguly

Neurotherapeutic technologies represent a diverse group of very promising treatment approaches with a common purpose of improving neurological function. Decades of basic science research has paved the path for these novel technologies that have the potential to transform the lives of patients with neurological diseases. A key goal is to minimize the consequences of lost abilities, whether it is motor, sensory, or cognitive. A common objective is to also harness the inherent plasticity of the nervous system, regardless of age, and even in the face of a degenerative process.

The technologies described below are the culmination of both an increased understanding of neural plasticity mechanisms in both the intact and the injured nervous system as well as advances in technology and computational power. There has been important progress in understanding neural plasticity at the level of the microscale (e.g., cellular and molecular processes), the mesoscale (e.g., between distinct cortical and subcortical areas), and the macroscale (e.g., at the level of brain networks). While it is also clear that there may be fundamental limits on plasticity (e.g., the closing of developmental windows) and repair mechanisms, the brain remains highly plastic regardless of age and even in the face of ongoing injury and/or degenerative processes. Collectively, there is now growing evidence to support neurological restorative efforts for both "static" (e.g., stroke) and progressive neurological disorders.

Importantly, while these technologies may not appear, at first glance, directly relevant to traditional medical care, it is worth noting that clinicians have the most knowledge and experience about the specific disease process, the treatments available, and the expected course of illnesses affecting the nervous system. It is thus critical that neurologic specialists and other clinicians can and should play an important role in the future adoption of these technologies for neurological rehabilitation. The sections below outline emerging diagnostic and therapeutic approaches that have the potential to transform the lives of patients with neurological disorders. These include technologies to harness plasticity, neuroimaging, neurostimulation, and brain–machine interfaces (BMIs).

TECHNOLOGIES TO HARNESS PLASTICITY

Neurological rehabilitation aims to harness activity-dependent plasticity mechanisms to maximize functional restoration. This principle can be applied to a diverse range of functional domains such as movement control, sensory processing, language, pain, and cognition. For example, recent randomized controlled clinical trials for motor recovery after stroke have suggested that intensity of training may be particularly important for sustained long-term improvements. Moreover, studies of the effects of such training in rodent and nonhuman primate models further suggest that plasticity of cortical "motor maps" might underlie the observed functional improvements. The incorporation of technology for neurological rehabilitation has the great potential to revolutionize the delivery of care by significantly increasing access, reducing the burden for adherence to high intensity regimens, and by maximizing engagement. Below are three examples of how emerging technology can be used to harness neural plasticity and to maximize functional restoration.

ROBOTICS

Rehabilitation robotics for both the upper and the lower limb have the potential to improve motor outcomes after stroke or other forms of brain injury. There is a growing recognition that focused training involving a range of tasks might be important for improved functional outcomes. While it remains unclear exactly when such training might be optimal after the initial stroke and during the early recovery period, such training likely has a role in both the acute and the chronic periods after stroke; maintenance therapy may also provide a guard against observed declines in function over time. Notably, the delivery of intensive training is a great challenge from both the perspective of the health care system and each patient. Outside of clinical trials, such a training program can be quite difficult to implement and maintain. It can also be costly and require significant effort.

Motor rehabilitation using robotics has been developed and tested for both the upper-limb and the lower-limb. Such robotic therapies have often focused on the delivery of high-intensity movement practice that can surpass what is possible via existing standards of care. Moreover, the robotic systems are capable of precisely measuring movement parameters (e.g., the kinematics of the movements) and providing quantitative feedback regarding the changes in performance during the training period. A particular focus has been on maximal patient engagement and recruitment of attentional and reward pathways, both of which are increasingly recognized to drive neural plasticity. Continued advances in design and the user interface will ensure maximal comfort and sustained effort. For example, via close monitoring of performance and movement parameters, the system can provide assistance at key points in order to minimize fatigue and to ensure maximal engagement. Moreover, antigravity support of the upper-limb can allow practice and task engagement even in the presence of severe weakness; this would be extremely challenging and labor intensive under current standards of care. Recent analysis also suggests that robotic devices may at least match outcomes realized with existing standards of care. However, rehabilitation robotics may also provide more precise feedback and permit novel quantitative rehabilitation approaches.

FIGURE 477-1 Photograph of a subject interacting with a complex upper-limb exoskeleton and a virtual reality system. *(From U Keller et al: Robot-Assisted Arm Assessments in Spinal Cord Injured Patients: A Consideration of Concept Study. PLoS One 10:e0126948, 2015.)*

Figure 477-1 shows one example of an upper-limb robotic exoskeleton device that is currently being evaluated for training after stroke. A recent randomized, multicenter trial compared treatment with this exoskeleton system against conventional therapy provided by physical and occupational therapists. Participants were enrolled in the chronic phase and all had moderate-to-severe deficits; the groups underwent three sessions per week over an 8-week period. For robotic training, subjects trained with games to improve mobilization and to practice activities of daily living. This study provided evidence that both conventional and robotic therapy could improve function in patients with chronic stroke. Multiple studies have also found similar gains when using either conventional or traditional approaches. Thus, a growing body of research supports the idea that such devices might complement current conventional approaches to rehabilitation. Future work will need to define how rehabilitation robotics can optimally use adaptive and quantitative methods to further augment the recovery process.

VIRTUAL AND AUGMENTED REALITY

Therapeutic approaches using Virtual Reality (VR) and Augmented Reality (AR) aim to treat neurological illnesses by specifically and quantitatively altering a patient's subjective experiences and interactions with the environment. Core components of both are advanced hardware and computational methods to generate simulated, yet realistic, perceptions. While some applications permit users to dynamically change the viewed perspective, other applications are designed to allow interactions among multiple users. Visual feedback is often a key component; this can include simple computer monitors or more immersive "head mounted" viewers that modify the simulation based on changes in perspective. Tracking of movements (e.g., hand and head position) are often included. Multiple methods are used to allow a user to interact with the environment. For example, interactions can be guided by straightforward means such as a keyboard, mouse or even a joystick. More immersive methods are also frequently used. For example, gloves with embedded sensors and haptic inputs can allow the user's hand to be represented in real time in the simulated environment. Moreover, haptic interfaces can provide sensory feedback, allowing patients to interact and "feel" virtual objects through multiple sensory modalities. A particular strength of these approaches is that any therapeutic intervention can be studied in very controlled environments.

VR enables a user to interact with a simulated reality that can be precisely and quantitatively controlled. In addition to allowing patients to dynamically experience an altered reality, it can simultaneously monitor a subject's behaviors and responses. Such monitoring can allow both precise measurements of clinically relevant parameters (e.g., motor actions, perception, cognitive processing) and for specific rehabilitation training that can attain clinically relevant goals. A growing body of literature indicates that VR environments can be tailored to individual needs and preferences, thereby maximizing engagement, motivation, and adaptation to ensure sufficient difficulty of tasks. VR environments can be designed to create powerful "gaming" platforms that are actually targeting clinically relevant parameters. For example, the upper-limb robotic systems described previously are frequently combined with VR environments that allow interaction with virtual objects.

In contrast to VR, AR overlays an artificial filter over a subject's view of the actual physical world, thus providing an "augmented" or enhanced view of the world around. AR is being tested in a diverse group of patients with neurological impairments in either the motor, sensory, or cognitive domains. AR may offer a particularly unique rehabilitation intervention for stroke patients. It is widely known that brain injuries limit each patient's physical interaction with their environment. Furthermore, physical and cognitive impairments may limit social interactions. Such impoverished experiences are likely to be present during both the acute and the chronic phases. Importantly, there is clear basic science evidence that environmental enrichment can be a key component of rehabilitation; such enrichment may offer additive benefits to the often limited formal rehabilitation sessions per week. Consistent with this are clinical studies suggesting that motor and cognitive outcomes may suffer when interactions with the environment are reduced. AR may be capable of increasing enrichment. For example, in the case of spatial neglect after stroke, the impaired modality may be accounted for using AR methods. Similarly, physical impairments that limit walking speeds can also limit visual feedback; both AR and VR can be used to enhance visual feedback during gait training.

Figure 477-2 shows a recent innovative application of AR for the treatment of "phantom limb" pain. A subset of both upper-limb and lower-limb amputees experience painful sensations that appear to originate from the missing limb. Past research has suggested that mirror therapy can be an effective treatment for phantom limb pain. During mirror therapy treatments, patients move their healthy arm in front of a mirror in order to produce a perception of movements of the missing limb. Previous studies have suggested that maladaptive plasticity of affected sensory cortices may be treated with mirror therapy. Importantly, in comparison to mirror therapy, AR-based therapy for phantom limb pain can be based on movements of the affected limb, i.e., the remaining limb portion as opposed to using the unaffected contralateral limb. This study demonstrated a novel treatment in which "phantom motor execution" is enabled using sophisticated machine learning algorithms. More specifically, the study "decoded" phantom limb movements by measuring electromyogram (EMG) activity at the stump. Importantly, while the distal muscles responsible for movements were lost as a result of amputation, the remaining EMG activity could be used to predict presumed distal limb movements. As shown in the figure, these inferred movements were projected onto an AR screen to create the perception of limb movements. The study showed that a subset of patients with long-term refractory phantom limb pain could experience a significant reduction in pain levels after using the AR system.

NEUROGAMING

Computerized programs that harness the power of "video games" have shown some evidence for ameliorating deficits in visual perception, age-related degeneration, and neuropsychiatric disorders. An essential feature of effective video game training is the progressive adjustment of the level of difficulty in line with the cognitive improvement of the patient. Important areas of active research include ways to enhance sustainability of neurogame training over long time periods and improving training *transfer*, i.e., the generalizability of task-specific training in one cognitive domain to more broad-based functional improvements. By leveraging video game technology, neurogames allow for dynamic user interaction and maintain user-engagement over multiple sessions over several days of training. Important game mechanics include repetitive practice, performance-adaptive challenges, and several layers of reward feedback—from moment-to-moment point rewards to reward milestones over multiple sessions.

FIGURE 477-2 Augmented reality (AR) for phantom limb pain. ***A.*** A patient is shown live Augmented Reality (AR) video. ***B.*** Electromyogram (EMG) electrodes placed over the stump record muscle activation during training. ***C.*** The patient matches target postures during rehabilitation. ***D.*** Patient playing a game in which a car is controlled by "phantom movements." *(From M Ortiz-Catalan et al: Phantom motor execution facilitated by machine learning and augmented reality as treatment for phantom limb pain: A single group, clinical trial in patients with chronic intractable phantom limb pain. Lancet 388:2885, 2016.)*

Notably, neurogames have therapeutic potential as they can be targeted to specific neurocognitive deficits. For instance, games have shown significant benefits in aging, by targeting speed of processing and training the abilities to multitask and suppress distractions. In each case, selective targeting is achieved by focusing the adaptive challenges to the neurocognitive domain of interest. Duration of response time windows available to the user or the level of interference is selectively targeted in the case of speed of processing training and interference training, respectively. In more recent research, it was demonstrated that it is possible to engender focused circuit neuroplasticity using such selective targeting in neurogaming. For example, older adults learned to adaptively perform within progressively more challenging distractor environments. Neuroplasticity selective to distractor processing was evidenced in this study at both the microscale, i.e., at the resolution of single neuron spiking in sensory cortex, as well as macroscale, i.e., EEG (electroencephalography) based event-related potential recordings.

Video games have also shown promise in the treatment of visual deficits such as amblyopia and in cognitive remediation in neuropsychiatric disorders such as schizophrenia. However, while the evidence base has been encouraging in small sample randomized controlled studies (RCTs), larger RCTs are needed to demonstrate definitive therapeutic benefit. This is especially necessary as the commercial *brain training* industry continues to make unsubstantiated claims of the benefits of neurogaming; such claims have been formally dismissed by the scientific community. Like any other pharmacological or device-based therapy, neurogames need to be systematically validated in multiphase RCTs establishing neural target engagement, and documenting cognitive and behavioral outcomes in specific disorder populations.

Generalizability of training benefits from task-specific cognitive outcomes to more broad-based functional improvements remains the holy grail of neurogaming. Next-generation neurogames will aim to integrate physiological measures such as heart rate variability (an index of physical exertion), galvanic skin responses and respiration rate (indices of stress response), and even EEG-based neural measures. The objectives of such multimodal biosensor integration are to enhance the "closed-loop mechanics" that drive game adaptation and hence improve therapeutic outcomes and perhaps result in greater generalizability. These complex, yet potentially more effective, neurogames of the future will need rigorous clinical study for demonstration of validity and efficacy.

NEUROIMAGING

NEUROIMAGING OF CONNECTIVITY

Multimodal neuroimaging methods including fMRI (functional magnetic resonance imaging), EEG, and MEG (magnetoencephalography) are now being investigated as tools to study functional connectivity between brain regions, i.e., extent of correlated activity between brain regions of interest. Snapshots of functional connectivity can be analyzed while an individual is engaged in specific cognitive tasks or during rest. Resting state functional connectivity (rsFC) is especially attractive as a robust, task-independent measure of brain function that can be evaluated in diverse neurological and neuropsychiatric disorders. In fact, methodological research has shown that rs-fMRI can provide more reliable brain signals of energy consumption than specific task-based fMRI approaches.

In recent years, there has been a surge of research to identify robust rsFC-based biomarkers for specific neurological and neuropsychiatric disorders and thereby inform diagnoses, and even predict specific treatment outcomes. For many such disorders, the network level neurobiological substrates that correspond to the clinical symptoms are not known. Furthermore, many are not unitary diseases, but rather heterogeneous syndromes composed of varied co-occurring symptoms. Hence, the research quest for robust network biomarkers for complex neuropsychological disorders is challenging and still in its infancy. However, some studies have made significant headway in this domain. For example, in a large multisite cohort of ~1000 depressed patients, Drysdale et al. (2017) recently showed that rsFC measures can subdivide patients into four neurophysiological "biotypes" with distinct patterns of dysfunctional connectivity in limbic and frontostriatal networks. These biotypes were associated with different clinical-symptom profiles (combinations of anhedonia, anxiety, insomnia, anergia, etc.) and had high (>80%) diagnostic sensitivity and specificity. Moreover, these biotypes could also predict responsiveness to TMS (transcranial magnetic stimulation) therapy. Another recent study demonstrated utility of rsFC measures to predict diagnosis of mTBI (mild traumatic brain injury), which is clinically challenging by conventional means.

Apart from fMRI-based measures of rsFC, EEG- and MEG-based rsFC measures are also being actively investigated, as these provide a relatively lower cost alternative to fMRI. While EEG is of lowest cost, it compromises on spatial resolution. The major strength of MEG is its ability to provide more accurate source-space estimates of functional oscillatory coupling than EEG as well as provide measures at various physiologically relevant frequencies (up to 50 Hz shown to be clinically useful). In this regard, EEG/MEG are complementary to fMRI, which can only be used to study slow activity fluctuations (i.e., <0.1 Hz); the potential for EEG/MEG modalities to provide valid diagnostic biomarkers is currently underexploited and requires further study.

CLOSED-LOOP NEUROIMAGING

Neuroscientific studies to date are predominantly designed as "open-loop experiments," interpreting the neurobiological substrates of human behavior via correlation with simultaneously occurring neural activity. In recent years, advances in real-time signal processing have paved the way for "closed-loop neuroimaging," wherein humans can directly manipulate experiment parameters in real-time based on specific brain signals **(Fig. 477-3)**. Closed-loop imaging methods can not only advance our understanding of dynamic brain function but also have therapeutic potential. Humans can learn to modulate their neural dynamics in specific ways when they are able to perceive (i.e., see/hear) their brain signals in real-time using closed-loop neuroimaging-based neurofeedback. Early studies showed that such neurofeedback learning and resulting neuromodulation could be applied as therapy for patients suffering from chronic pain, motor rehabilitation in Parkinson's and stroke patients, modulation of aberrant oscillatory activity in epilepsy, and improvement of cognitive abilities such as sustained attention in healthy individuals and patients with attention deficit hyperactivity disorder (ADHD). It has also shown potential for deciphering state of

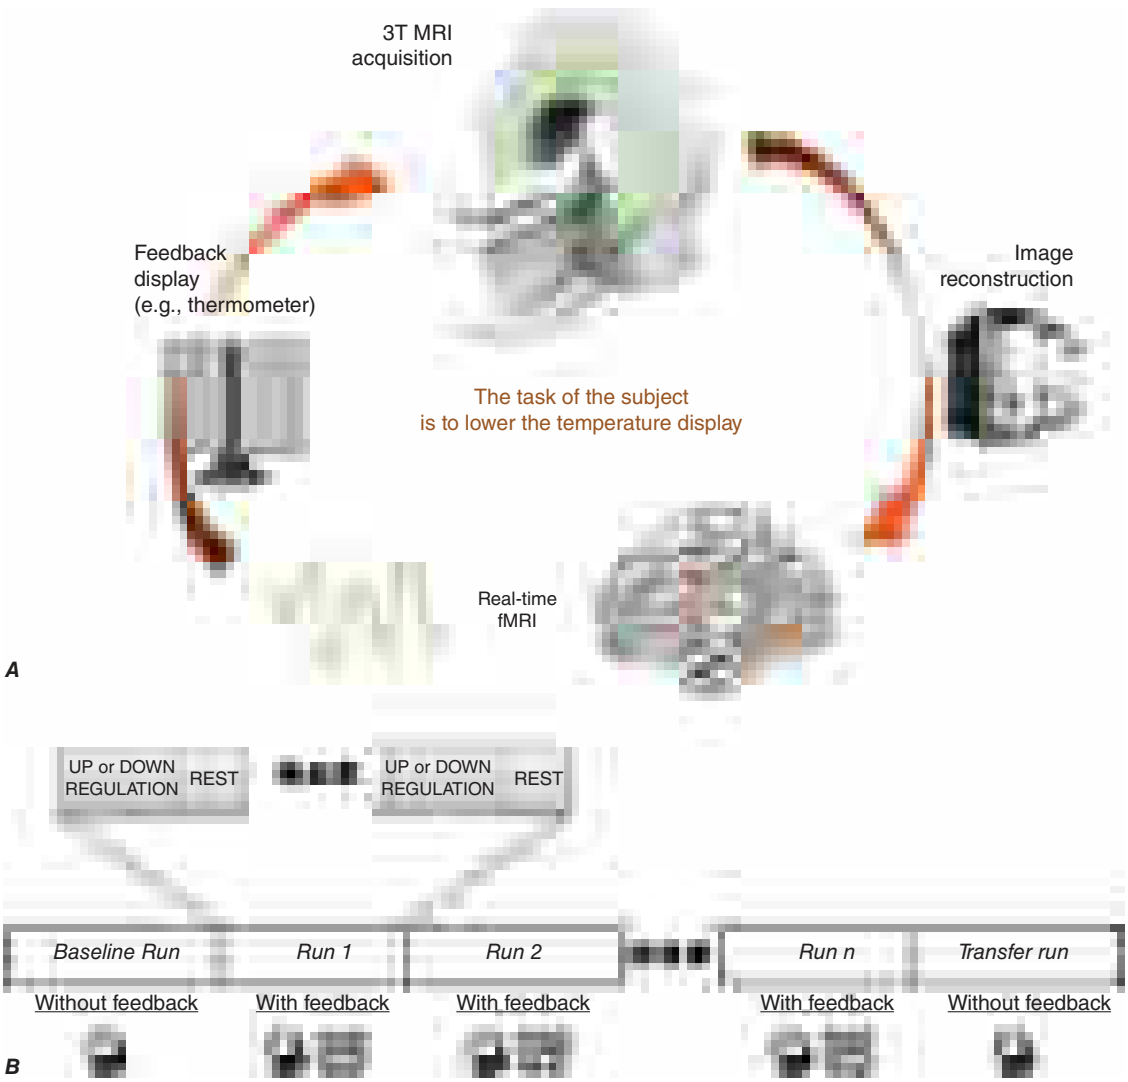

FIGURE 477-3 Neurofeedback using functional MRI. *(From T Fovet et al: Translating neurocognitive models of auditory-visual hallucinations into therapy. Front Psychiatry 7:103, 2016.)*

consciousness in comatose patients, wherein a proportion of vegetative/minimally conscious patients could communicate awareness via neuroimaging-based mental imagery.

Closed-loop neuroimaging therapeutic studies have utilized real-time fMRI, EEG, and MEG methods. It is common for neural signals to be extracted from specific target brain regions for neuromodulation. However, given that distributed neural networks underlie behavioral deficits, new studies have also explored neurofeedback on combinatorial brain signals from multiple brain regions extracted using multivariate pattern analysis (MVPA). While early studies indicate therapeutic potential, clinical RCTs of closed-loop neuroimaging neurofeedback have shown mixed results. This may largely be because of the individual heterogeneity in neuropsychiatric disorders such that there is no one-size-fits-all therapy. Closed-loop neuroimaging–based therapies need to be better personalized to the preintervention cognitive and neurophysiological states of the individual, and a better understanding needs to be developed regarding learning principles and mechanisms of self-regulation underlying neurofeedback. Clinical practitioners applying these methods also need better education on the hardware/software capabilities of these brain–computer interfaces to maximize patient outcomes.

NONINVASIVE BRAIN STIMULATION (NIBS)

NIBS is widely recognized as having great potential to modulate brain networks in a range of neurological and psychiatric diseases; it is currently approved by the U.S. Food and Drug Administration (FDA) as a treatment for depression. Importantly, there is a very large body of basic research indicating that neuromodulation of the nervous system with electrical stimulation can have both short-term and long-term effects. While TMS uses magnetic fields to generate electrical currents, transcranial direct current stimulation (tDCS), in contrast, is based on direct stimulation using electrical currents applied at the scalp **(Fig. 477-4)**. TMS induces small electrical currents in the brain by magnetic fields which pass through the skull; it is known to be painless and therefore widely used for noninvasive stimulation. Animal research suggests that anodal tDCS causes a generalized reduction in resting membrane potential over large cortical areas, whereas cathodal stimulation causes hyperpolarization. Prolonged stimulation with tDCS can cause an enduring change in cortical excitability under the stimulated regions. Further, changes in resting state fMRI-based activity and functional connectivity have also been observed post-tDCS. Notably, there is uncertainty regarding precisely how much electrical current is able to penetrate through the skull and modulate neural networks.

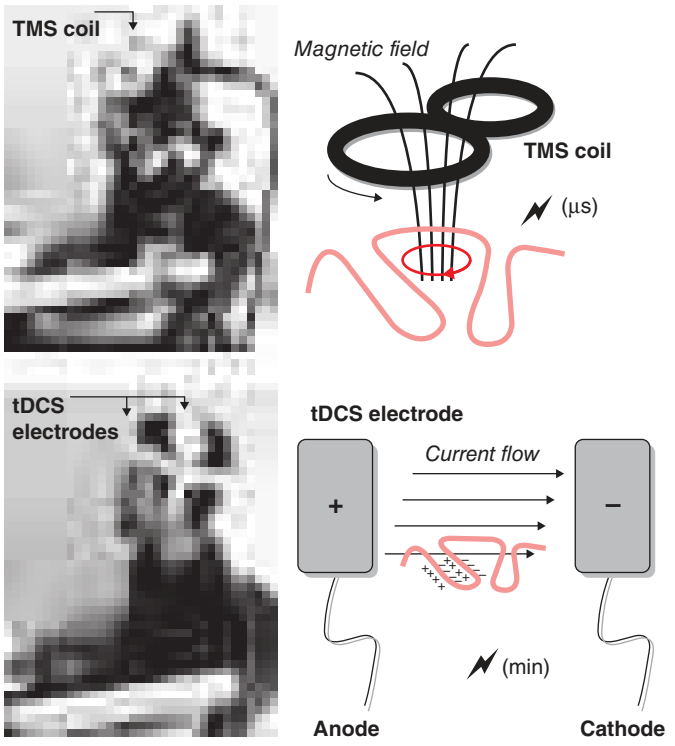

FIGURE 477-4 Illustration of TMS and tDCS setups. The upper panels show a TMS setup. Coils generate magnetic fields that can in turn generate electrical fields in the cortical tissue. The lower panels show a tDCS setup. The electrical current is believed to flow from the anode (+) to the cathode (−) through the superficial cortical areas leading to polarization. *(From R Sparing, FM Mottaghy: Noninvasive brain stimulation with transcranial magnetic or direct current stimulation [TMS/tDCS]—From insights into human memory to therapy of its dysfunction. Methods 44:329, 2008.)*

Neuromodulation via stimulation techniques such as tDCS and TMS have shown promise as methods to improve motor function after stroke; there are a growing number of studies demonstrating functional benefits of combining physical therapy with brain stimulation. Two commonly utilized TMS paradigms include low-frequency "inhibitory" stimulation of the healthy cortex or high frequency "excitatory" stimulation of the injured hemisphere. Each of these two approaches aims to modify the balance of reciprocal inhibition between the two hemispheres after stroke. A recent meta-analysis of randomized controlled trials published over the past decade found a significant beneficial effect on motor outcomes. Planned large multicenter trials to assess the long-term benefits of TMS on motor recovery after stroke should provide additional important information on this topic.

TMS and tDCS interventions are also being applied in psychiatric disorders. A substantial body of evidence supports the use of TMS as an antidepressant in MDD (major depressive disorder). TMS is also being investigated for its potential efficacy in posttraumatic stress disorder (PTSD), obsessive compulsive disorder (OCD), and treatment of auditory hallucinations in schizophrenia. Various repetitive TMS (rTMS) protocols have shown efficacy in major depression. These include both low frequency (≤1 Hz) and high frequency rTMS (10–20 Hz) stimulation over dorsolateral prefrontal cortex (DLPFC). Mechanistically, low frequency rTMS is associated with decreased regional cerebral blood flow while high frequency rTMS elicits increased blood flow, not only over the prefrontal region where the TMS is applied, but also in associated basal ganglia and amygdala circuits. Notably, the differential mechanisms of the low versus high frequency rTMS protocols are associated with mood improvements in different sets of MDD patients, and patients showing benefits with one protocol may even show worsening with the other, again pointing to individual heterogeneity in network function. EEG-guided TMS is also being investigated in psychiatric disorders, for instance, individual resting alpha-band (8–12 Hz) peak frequency to determine TMS stimulation rates. With respect to transcranial electrical stimulation in psychiatry, tDCS is the most commonly used protocol. In major depression, there is a documented imbalance in left versus right DLPFC activity, hence, differential anodal versus cathodal tDCS in the left versus right prefrontal cortex may be a potentially efficacious approach. Interestingly, while meta-analysis shows promise for noninvasive brain stimulation methods in psychiatric illness, large RCTs have failed to generate effects compared to placebo treatment. Future success may require careful personalized targeting based on network dynamics and refinement of protocols to accommodate combinatorial treatments.

IMPLANTABLE NEURAL INTERFACES INCLUDING BMIs

Fully implantable clinically relevant neural interfaces that can improve function already exist. Cochlear implants, for example, are sensory prostheses that can restore hearing in deaf patients. Real-time processing of environmental sounds is converted into patterned stimulation delivered to the cochlear nerve. Importantly, even while the patterned stimulation remains the same, there are gradual improvements in the perception of speech and other complex sounds over a period of several months after device implantation. Activity-dependent sculpting of neural circuits is hypothesized to underlie the observed perceptual improvements. Similarly, the development of deep-brain stimulation (DBS) was based on decades of work showing that surgical lesions to specific nuclei could alleviate tremor and bradykinesia symptoms in animal models. DBS involves chronic implantation of a stimulating electrode that targets specific neural structures (e.g., subthalamic nuclei or the globus pallidus in Parkinson's disease). At least for movement disorders, it is commonly thought that targeted areas are functionally inhibited by the chronic electrical stimulation.

BMIs represent a more advanced neural interface that aims to restore motor function. Multiple neurological disorders (e.g., traumatic and nontraumatic spinal cord injury, motor-neuron disease, neuromuscular disorders, and strokes) can result in severe and devastating paralysis. Patients cannot perform simple activities and remain fully dependent for care. Especially in patients with high cervical injuries, advanced amyotrophic lateral sclerosis (ALS) or brain-stem strokes, the effects are especially devastating and often leave patients unable to communicate. While there has been extensive research into each disorder, little has proven to be clinically effective for rehabilitation of long-term disability. BMIs offer a promising means to restore function. In the patients described above, while the pathways for transmission of signals to muscles are disrupted, the brain itself is largely functional. Thus, BMIs can restore function by communicating directly with the brain. For example, in a "motor" BMI, a subject's intention to move is translated in real-time to control a device. As illustrated in **Fig. 477-5**, the components of a motor BMI include: (1) recordings of neural activity, (2) algorithms to transform the neural activity into control signals, (3) an external device driven by these control signals, and (4) feedback regarding the current state of the device.

Many sources of neural signals can be used in a BMI. While EEG signals can be obtained noninvasively, other neural signals require invasive placement of electrodes. Three invasive sources of neural signals include electrocorticography (ECoG), action potentials or spikes, and local field potential (LFP). Spikes and LFP are recorded with electrodes that penetrate the cortex. Spikes represent high-bandwidth signals (300–25,000 Hz) that are recorded from either single neurons ("single unit") or multiple neurons ("multiunit" or MUA). LFPs are the low frequency (~0.1–300 Hz) components. In contract, ECoG is recorded from electrodes that are placed on the cortical surface. ECoG signals may be viewed as an intermediate resolution signal in comparison to spikes/LFP and EEG. It is worth noting that there is still considerable research into the specific neural underpinning of each signal source and what information can be ultimately extracted regarding neural processes.

A critical component of a BMI is the transform of neural activity into a reliable control signal. The decoder is an algorithm that converts the neural signals into control signals. One important distinction between classes of decoders is biomimetic versus nonbiomimetic. In the case of biomimetic decoders, the transform attempts to capture the natural relationship between neural activity and a movement parameter. In contrast, nonbiomimetic decoders can be more arbitrary transforms between neural activity and prosthetic control. It had been hypothesized that learning prosthetic control with a biomimetic decoder is more intuitive. Recent evidence, however, reveals that learning may be important for achieving improvements in the level of control over an external device (e.g., a computer cursor, a robotic limb) for either type of decoder. This may be like learning a new motor skill.

A central goal of the field of BMIs is to improve function in patients with permanent disability. This can consist of a range of communication and assistive devices such as a computer cursor, keyboard control, wheelchairs, or a robotic limb. In the ideal scenario, the least invasive method of recording neural signals would allow the most complex level of control. Moreover, control should be allowed in an intuitive manner that resembles the neural control of our natural limbs. There is currently active research into developing and refining techniques to achieve the most complex control possible using each signal source. One measure of complexity is the degrees of freedom that are controlled. For example, control of a computer cursor on the screen (i.e., on the "x" and "y" axis) represents 2 degrees of freedom (DOF). Control of a fully functional prosthetic upper arm that approaches our natural range of motion would require >7 DOF. If the functionality of the hand and fingers are included, then an even more complex level of control would be required. There has been a large body of research on the use of noninvasive recording of EEG signals. Studies suggest that 2 DOF control using EEG is feasible. There are also promising reports of patients with advanced ALS communicating via email using EEG–based BMI. Known limitations of EEG-based BMIs include its "signal-to-noise" ratio (due to filtering of neural signals by bone and skin) and contamination by muscle activity. Ongoing research aims to test usability in a more general nonresearch setting as well as targeted use in patients with disability.

Numerous studies now also indicate that BMIs using invasive recording of neural signals can allow rapid control over devices with multiple DOF. The clear majority of this research has been conducted using recordings of spiking activity via implanted microelectrode arrays. Initial preclinical studies were performed in able-bodied nonhuman primates. More recently, there have been numerous examples of human subjects with a range of neurological illnesses (e.g., brainstem stroke, ALS, spinal cord injury) who have demonstrated the actual use of implantable neural interfaces. This includes demonstrations of both the control of communication interfaces as well as robotic limbs. Pilot clinical trials of BMIs based on invasive recordings of neural signals have further shown that significantly greater rates of communication are possible (e.g., 15–30 characters per minute). Notably, these BMI devices required a percutaneous connection and were always tested in the presence of research staff. A recent case study additionally demonstrated that a fully implantable BMI system could allow communication in a locked-in ALS patient **(Fig. 477-6)**. At the time of the study, the patient required mechanical ventilation and could only communicate using eye movements. She was implanted with multiple subdural cortical electrodes; the neural signals were then processed and sent wirelessly to an external AAC (augmentative and alternative communication) system. Importantly, she could use the interface with no supervision from research staff.

BMIs have the potential to revolutionize the care of neurologically impaired patients. While in its infancy, there have been multiple proof-of-principle studies that highlight possibilities. Combined basic and clinical efforts will ultimately lead to the development of products that are designed for patients with specific disabilities. As outlined earlier, each signal source has strengths (e.g., noninvasive vs invasive, recording stability) and weaknesses (e.g., bandwidth or the amount of information that can be extracted). With additional research a more precise delineation of these strengths and weakness should occur. For example, one hypothesis is that control of complex devices with high DOF will only be possible using invasive recordings of high-resolution neural activity such as spikes from small clusters of neurons. As these limits become increasingly clear it should allow targeted clinical translational efforts that are geared to specific patient needs and preferences (e.g., extent of disability, medical condition, noninvasive vs invasive). For example, patients with high cervical injuries (i.e., above C4, where the arm and the hand are affected) have different rehabilitation needs

than patients with lower cervical injuries (i.e., below C5–C6, where the primary deficits is the hand and fingers).

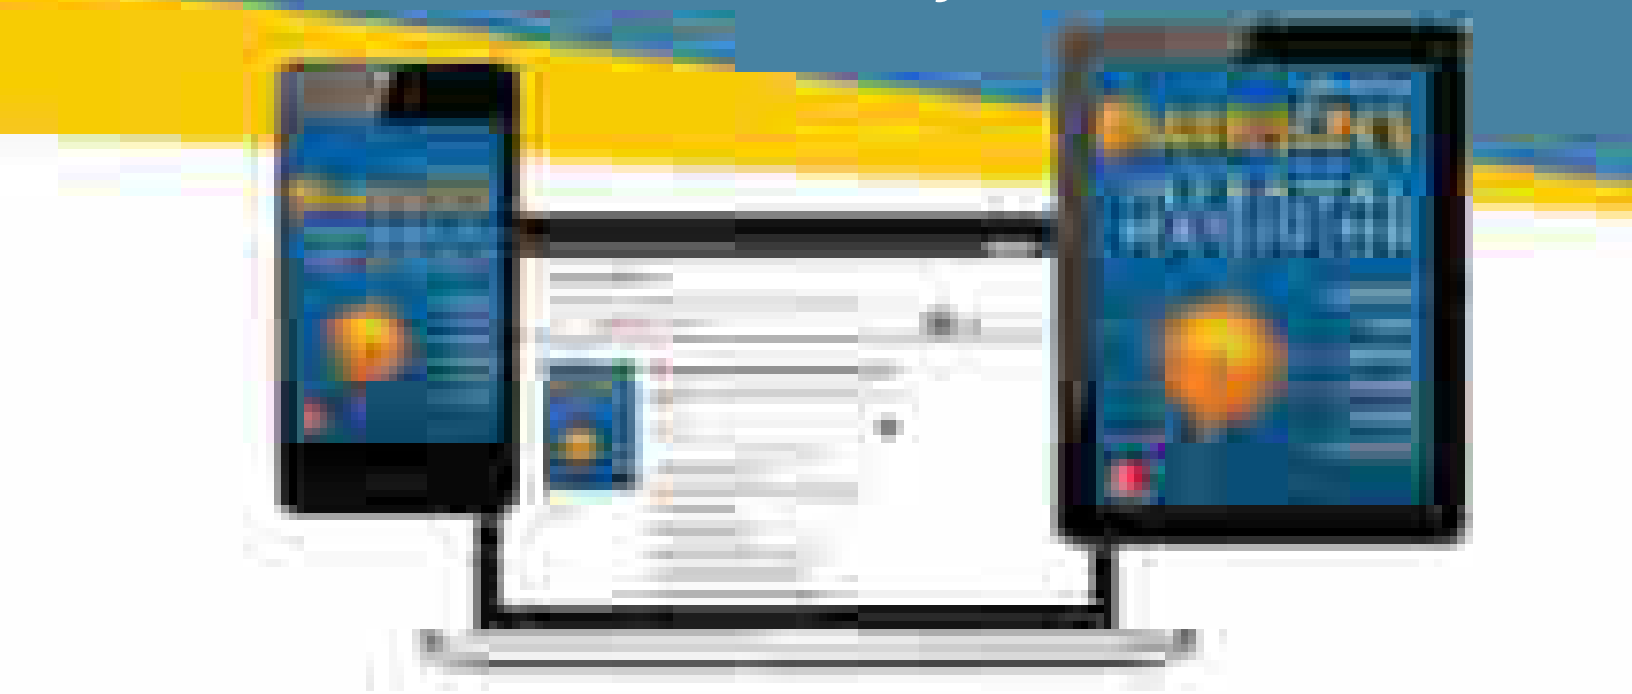
Try AccessMedicine FREE for 30 Days!

Consult the brightest, most respected minds in medicine on any device



AccessMedicine delivers the complete spectrum of medical knowledge for learning and practice. With AccessMedicine® faculty and students can quickly and easily tap into a collection of authoritative, trusted medical references – **including the new twentieth edition of *Harrison's Principles of Internal Medicine.***

- Practicing physicians can stay current with their medical knowledge and contribute to better patient outcomes
- Residents, NPs, and PAs have instant access to videos, Q&A, and leading medical textbooks that facilitate decision-making at the point-of-care
- Students learn from the world's most respected medical resources and references to gain a clear understanding of basic and clinical sciences.

McGraw-Hill Education also offers institutions access to a suite of other online medical resources. From pharmacology to pediatrics, surgery to physiology, the Access suite of online products covers everything necessary to ace the test, complete a successful rotation, and succeed in a medical career within every medical specialty.

To request an institutional **FREE, 30-DAY TRIAL** of AccessMedicine or any of our other products, visit:
